Chapter 532 - Obstructions of the Urinary Tract

Obstructive lesions of the urinary tract occur at any level from the urethral meatus to the calyceal infundibula. Obstruction can be congenital (anatomic) or caused by trauma, neoplasia, calculi, inflammatory processes, or surgical procedures (Table 532–1). The pathophysiologic effects of obstruction depend on its level, extent of involvement, age at onset, and acute or chronic nature. In childhood, most obstructive lesions are congenital.

Etiology.

Severe ureteral obstruction of early onset in fetal life results in renal dysplasia, ranging from the multicystic kidney, usually associated with ureteral or pelvic atresia (see Fig. 529–2), to various degrees of histologic renal cortical dysplasia

TABLE 532-1 -- **Types and Causes of Urinary Tract Obstruction**

Location	Cause
Infundibula	Congenital
	Calculi
	Inflammatory (tuberculosis)
	Traumatic
	Postsurgical
	Neoplastic
Renal pelvis	Congenital (infundibulopelvic stenosis)
	Inflammatory (tuberculosis)
	Calculi
	Neoplasia (Wilms tumor, neuroblastoma)

	Inflammatory (Crohn disease, chronic granulomatous disease)
	Hematoma, urinoma
	Lymphocele
	Retroperitoneal fibrosis

Bladder outlet and urethra	Neurogenic bladder dysfunction (functional obstruction)
	Posterior urethral valves
	Anterior urethral valves
	Diverticula
	Urethral strictures (congenital, traumatic, or iatrogenic)
	Urethral atresia
	Ectopic ureterocele
	Meatal stenosis (males)
	Calculi
	Foreign bodies
	Phimosis
	Extrinsic compression by tumors
	Urogenital sinus anomalies

seen with less severe obstruction. Chronic ureteral obstruction in late fetal life or after birth results in dilatation of the ureter, renal pelvis, and calyces, with alterations of renal parenchyma ranging from minimal tubular changes to dilatation of Bowman space, glomerular fibrosis, and interstitial fibrosis. After birth, infections often complicate obstruction and may increase renal damage.

Clinical Manifestations.

Urinary tract obstruction generally causes hydronephrosis, which typically is asymptomatic in its early phases. An obstructed kidney secondary to a ureteropelvic junction (UPJ) or ureterovesical junction obstruction may cause upper abdominal or flank pain on the affected side; pyelonephritis may occur because of urinary stasis. Occasionally, an upper urinary tract stone occurs, which can cause abdominal and flank pain and hematuria. With bladder outlet obstruction, the urinary stream may be weak; urinary tract infection (UTI) is common. Many of these lesions are identified by antenatal ultrasonography; an abnormality involving the genitourinary tract is suspected in as many as 1 in 100 fetuses.

Obstructive renal insufficiency can manifest itself by failure to thrive, vomiting, diarrhea, or other nonspecific signs and symptoms. In older children, infravesical obstruction can be associated with overflow urinary incontinence or a poor urinary stream. Acute ureteral obstruction causes flank or abdominal pain; there may be nausea and vomiting. Chronic ureteral obstruction can be silent or can cause vague abdominal or typical flank pain with increased fluid intake.

Diagnosis.

Urinary tract obstruction is often silent. In the newborn infant, a palpable abdominal mass is most commonly a hydronephrotic or multicystic dysplastic kidney. With infravesical obstructive lesions in boys, a walnut-sized mass, representing the bladder, is palpable just above the pubic symphysis. A patent urachus should suggest urethral obstruction. Urinary ascites in the newborn usually is caused by renal or bladder urinary extravasation secondary to posterior urethral valves.

Urinary tract obstruction may be diagnosed prenatally by ultrasonography, typically showing hydronephrosis. Further ultrasonography and a more complete evaluation should be undertaken in the neonatal period. Infection and sepsis may be the first indications of an obstructive lesion of the urinary tract. The combination of infection and obstruction poses a serious threat to infants and children and usually requires parenteral administration of antibiotics and drainage of the obstructed kidney. Renal ultrasonography should be performed in all children during the acute stage of febrile urinary tract infections.

IMAGING STUDIES

Renal Ultrasonography. The common characteristic of obstruction is the presence of a dilated urinary tract. Hydronephrosis is frequently an ultrasonographic finding (Fig. 532–1). Dilatation is not always indicative of obstruction and may persist after surgical correction of an obstructive lesion. Dilatation may result from vesicoureteral reflux, or it may be a manifestation of abnormal development of the urinary tract, even when there is no obstruction. Renal length, degree of caliectasis and parenchymal thickness, and presence or absence of ureteral dilatation should be assessed. Ideally, the severity of hydronephrosis should be graded from 1 to 4 using the Society for Fetal Urology grading scale (Table 532–2). One may ascertain that the contralateral kidney is normal, and the bladder should be imaged to see whether the bladder wall is thickened, the lower ureter is dilated, and whether bladder emptying is complete. In acute or intermittent obstruction, the dilatation of the collecting system may be minimal and ultrasonography may be misleading.

Voiding Cystourethrogram (VCUG). In all cases of congenital hydronephrosis and in any child with ureteral dilatation, a VCUG should be obtained, because the dilatation is secondary to vesicoureteral reflux in 15% of cases. In males, the VCUG also is necessary to rule out urethral obstruction, particularly in cases of suspected posterior urethral valves. In infravesical obstruction in infants, the bladder may be palpable because of chronic distention and incomplete emptying. In older children, the urinary flow rate can be measured noninvasively with a

TABLE 532-2 -- **Society for Fetal Urology Grading System for Hydronephrosis**

Grade of Hydronephrosis	**Renal Image**	
	Central Renal Complex	***Renal Parenchymal Thickness***

0	Intact	Normal
1	Slight splitting	Normal
2	Evident splitting, complex confined within renal border	Normal
3	Wide splitting pelvis dilated outside renal border, calyces uniformly dilated	Normal
4	Further dilatation of pelvis and calyces (calyces may appear convex)	Thin

Figure 532-1 Ultrasonographic image of the left kidney with marked pelvic and calyceal dilatation (grade IV hydronephrosis) in a boy with ureteropelvic junction obstruction.

urinary flowmeter and decreased flow with a normal bladder contraction is suggestive of infravesical obstruction. When the urethra cannot be catheterized to obtain a VCUG, one must suspect a urethral stricture or an obstructive urethral lesion. Retrograde urethrography with contrast medium injected into the urethral meatus helps delineate the anatomy of the urethral obstruction.

Radioisotope Studies. Renal scintigraphy is used to assess renal anatomy and function. The two most common radiopharmaceuticals are mercaptoacetyl triglycine (MAG-3) and technetium-99m-labeled dimercaptosuccinic acid (DMSA). MAG-3 is excreted by renal tubular secretion; it is used to assess differential renal function and, when furosemide is administered, drainage can also be measured. An alternative to MAG-3 is diethylene tetrapentaacetic acid (DTPA), which is cleared by glomerular filtration. The background activity of DTPA is much higher than MAG-3. DMSA is a renal cortical imaging agent and is used to assess differential renal function and to demonstrate whether renal scarring is present. It is used infrequently in children with obstructive uropathy.

In a *MAG-3 diuretic renogram,* a small dose of technetium-labeled MAG-3 is injected intravenously (Figs. 532–2 and 532–3). During the first 2 to 3 min, renal parenchymal uptake is analyzed and compared, allowing computation of differential renal function. Subsequently, excretion is evaluated. After 20 to 30 min, furosemide is injected intravenously and the rapidity and pattern of drainage from the kidneys to the bladder are analyzed. If no obstruction is present, half of the radionuclide should be cleared from the renal pelvis within 10 to 15 min, termed the half-life (t½). If there is significant upper tract obstruction, the t½ generally is greater than 20 min. A t½ between 15 and 20?min is indeterminate. The images generated usually provide an accurate assessment of the site of obstruction. Numerous variables affect the outcome of the diuretic renogram. For example, newborn kidneys are functionally immature and, in some cases, normal kidneys may not demonstrate normal drainage after

Figure 532-2 MAG-3 diuretic renogram in a 6-wk-old infant with right hydronephrosis detected by prenatal ultrasonography. The right kidney is on the right side of the image. *A*, Differential renal function: left kidney 70%, right kidney 30%. *B*, After administration of furosemide, drainage from the left kidney was normal and drainage from the right kidney was slow, consistent with right ureteropelvic junction obstruction. Pyeloplasty was performed on the right kidney.

Figure 532-3 Same patient as in Figure 532–2 . *A* and *B*, MAG-3 diuretic renogram at 14 mo of age shows equal function in the two kidneys and prompt drainage after the administration of furosemide.

diuretic administration. Dehydration prolongs parenchymal transit and can blunt the diuretic response. Giving an insufficient dose of furosemide may result in inadequate drainage. If vesicoureteral reflux is present, continuous catheter drainage is mandatory to prevent the radionuclide from refluxing from the bladder into the dilated upper tract, which would prolong the washout phase. Because of the numerous variables, the Society for Fetal Urology and the Pediatric Nuclear Medicine Club jointly developed a standardized method for performing diuretic renography in infants and children termed the *well-tempered renogram*.

The MAG-3 diuretic renogram is considered superior to the excretory urogram in infants and children with hydronephrosis because bowel gas and immaturity of renal function often cause the intravenous pyelogram (IVP) images to be suboptimal. In addition, the diuretic renogram provides an objective assessment of the relative

function of each kidney.

Excretory Urogram (IVP). The IVP is used infrequently for imaging the urinary tract in children but is useful in selected cases (Fig. 532–4). The plain film of the abdomen should be inspected for calculi, spinal abnormalities, and an abnormal intestinal gas pattern or severe constipation. In infravesical obstruction, the bladder wall is irregular or trabeculated because of detrusor hypertrophy. A postvoid film may show residual bladder urine. In ureteral obstruction, there is dilatation of the collecting system above the obstruction and blunting of the calyces. Concentration of the radiopaque medium on the obstructed side is impaired, and there may be a delayed appearance of contrast medium in the collecting system with progressive increase in concentration at the point of obstruction when delayed radiographs are obtained. In high-grade obstruction, the contrast agent may remain in the collecting system after 24?hr.

Urinary extravasation can be detected in the early or delayed films of a urographic study as well as on an MAG-3 renogram. When intermittent obstruction is suspected, intravenous urography during an acute episode of pain is often the most valuable diagnostic study.

Computed Tomography. In children with a suspected ureteral calculus, noncontrast spiral computed tomography of the abdomen and pelvis provides an excellent method of demonstrating whether a calculus (or calculi) is present, its location, and whether there is significant proximal hydronephrosis. This study is the initial study of choice in these patients.

Ancillary Studies. In unusual cases, another way to assess the anatomy of the upper urinary tract is by inserting a percutaneous nephrostomy tube and injecting contrast agent, termed an ***antegrade pyelogram.*** This procedure usually requires general anesthesia. In addition, an antegrade pressure-perfusion flow study, a ***Whitaker test***, may be performed, in

Figure 532-4 Ureteropelvic junction obstruction. Excretory urogram in a boy, showing dilatation of the left renal pelvis and blunting of the calyces characteristic of a ureteropelvic junction obstruction.

Figure 532-5 Retrocaval ureter. Retrograde pyelogram showing medial deviation of a dilated upper ureter to the level of the 3rd lumbar vertebra, characteristic of a retrocaval ureter.

which fluid is infused at a measured rate, usually 10?mL/min. The pressures in the renal pelvis and the bladder are monitored during this infusion, and pressure differences exceeding 20?cm H_2O are suggestive of obstruction. In other cases, cystoscopy with retrograde pyelography provides excellent images of the upper urinary tract (Fig. 532–5).

SPECIFIC TYPES OF URINARY TRACT OBSTRUCTION AND THEIR TREATMENT

Hydrocalycosis.

This term refers to a localized dilatation of the calyx caused by obstruction of its infundibulum, termed *infundibular stenosis.* Such obstruction can be developmental in origin or secondary to inflammatory processes, such as UTI. When the abnormality is not discovered by antenatal ultrasonography or incidentally, it is usually discovered during evaluation for pain or UTI. The diagnosis of infundibular stenosis is usually established by IVP.

UPJ Obstruction.

This is the most common obstructive lesion in childhood and is usually caused by intrinsic stenosis (see Figs. 532–1 through 532–4). At times an accessory artery to the lower pole of the kidney also causes extrinsic obstruction. The typical appearance on ultrasonography is grade 3 or 4 hydronephrosis without a dilated ureter. UPJ obstruction most commonly presents (1) on maternal ultrasonography revealing fetal hydronephrosis; (2) as a palpable renal mass in a newborn or infant; (3) as abdominal, flank, or back pain; (4) as a febrile UTI; or (5) as hematuria after minimal trauma. Approximately 60% of cases occur on the left side, and the male:female ratio is 2:1. Ten percent of UPJ obstructions are bilateral. In kidneys with UPJ obstruction, renal function may be significantly impaired from pressure atrophy. The anomaly is corrected by performing a pyeloplasty, in which the stenotic segment is excised and the normal ureter and renal pelvis are reattached. Success rates are 91–98%.

Lesser degrees of UPJ obstruction may cause mild hydronephrosis, which usually is nonobstructive, and typically these kidneys function normally. The spectrum of UPJ abnormalities has been referred to as *anomalous UPJ*. Another cause of mild hydronephrosis is fetal folds of the upper ureter, which also are nonobstructive.

The diagnosis can be difficult to establish in an asymptomatic infant in whom dilatation of the renal pelvis is found incidentally in a prenatal ultrasonogram. After birth, the sonographic study is repeated to confirm the prenatal finding. A VCUG is necessary because 10–15% of patients have ipsilateral vesicoureteral reflux. If no dilatation is found after birth, a renal ultrasonogram should be repeated at 1 mo of age because the dilatation may be minimal immediately after birth secondary to transient oliguria but may become more evident a few weeks later. Consequently, it is best to perform the first postnatal ultrasonographic study after the 3rd day of life because oliguria in the newborn may mask the dilatation. If the kidney shows grade 1 or 2 hydronephrosis and the renal parenchyma appears normal, a period of observation is usually appropriate with sequential renal ultrasonograms to monitor the severity of hydronephrosis, and disappearance of the hydronephrosis usually occurs. The child should receive antibiotic prophylaxis, usually trimethoprim-sulfamethoxazole, although amoxicillin or cephalexin is preferable before 2 mo of age. If the hydronephrosis is grade 3 or 4, spontaneous resolution is less likely and obstruction is more likely to be present. A diuretic renogram with MAG-3 is performed at 4–6 wk of age. If there is poor upper tract drainage or the differential renal function is poor, pyeloplasty is recommended. After pyeloplasty the differential renal function often improves and improved drainage with furosemide

stimulation is expected.

If the differential function on renography is normal and drainage is satisfactory, the infant can be followed with serial ultrasonograms. If the hydronephrosis remains severe with no improvement, a repeat diuretic renogram after 6–12 mo may help in the decision between continued observation and surgical repair. Prompt surgical repair is indicated in infants with an abdominal mass, bilateral severe hydronephrosis, a solitary kidney, or diminished function in the involved kidney. In unusual cases the differential renal function is less than 10% but the kidney definitely has some function. In this situation, insertion of a percutaneous nephrostomy tube allows drainage of the hydronephrotic kidney for a few weeks to allow reassessment of renal function. In older children who present with symptoms, the diagnosis of UPJ obstruction usually is established by ultrasonography and diuretic renography.

In the *differential diagnosis*, the following entities should be considered: (1) megacalycosis, a congenital nonobstructive dilatation of the calyces without pelvic or ureteric dilatation; (2) vesicoureteral reflux with marked dilatation and kinking of the ureter; and (3) midureteral or distal ureteral obstruction when the ureter is not well visualized on the urogram.

Midureteral Obstruction.

Congenital ureteral stenosis or a ureteral valve in the midureter is rare and is corrected by excision of the strictured segment and reanastomosing the normal upper and lower ureteral segments. A *retrocaval ureter* is an anomaly in which the upper right ureter travels posterior to the inferior vena cava. In this anomaly, the vena cava may cause extrinsic compression and obstruction. An IVP shows the right ureter to be medially deviated at the level of the 3rd lumbar vertebra. The diagnosis may be confirmed by retrograde pyelography (see Fig. 532–5). Surgical treatment consists of transection of the upper ureter, moving it anterior to the vena cava, and reanastomosing the upper and lower segments. Repair is necessary only when obstruction is present. Retroperitoneal tumors, fibrosis caused by surgical procedures, inflammatory processes (as in chronic granulomatous disease), and radiation therapy can cause acquired midureteral obstruction.

Figure 532-6 Ultrasonographic image of the right dilated ureter (*thin arrows*) extending behind and caudal to a nearly empty bladder (*arrow*) in a girl with urinary incontinence and ectopic ureter draining into the vagina.

Ectopic Ureter.

An ectopic ureter refers to a ureter that drains outside the bladder. They are three times as common in girls as in boys. The ectopic ureter usually drains the upper pole of a duplex collecting system (i.e., two ureters). In girls, approximately 35% enter the urethra at the bladder neck, 35% enter the urethrovaginal septum, 25% enter the vagina, and a few drain into the cervix, uterus, Gartner duct, or a urethral diverticulum. With the exception of the ectopic ureter entering the bladder neck, all cause continuous urinary incontinence from the affected renal moiety. In addition, UTI is common because of urinary stasis. In boys, ectopic ureters enter the posterior urethra (above the external sphincter) in 47%, the prostatic utricle in 10%, the seminal vesicle in 33%, the ejaculatory duct in 5%, and the vas deferens in 5%. Consequently, in boys, an ectopic ureter does not cause incontinence, and most patients present with a UTI or epididymitis. Evaluation includes a renal sonogram, VCUG, and renal scan, which demonstrates whether the affected segment has significant function. The sonogram shows the affected hydronephrotic kidney or dilated upper pole and ureter down to the bladder (Fig. 532–6). If the ectopic ureter drains into the bladder neck (female), a VCUG usually shows reflux into the ureter. Otherwise, there is no reflux into the ectopic ureter, but there may be reflux into the ipsilateral lower pole ureter or contralateral collecting system.

Treatment depends on the status of the renal unit drained by the ectopic ureter. If there is satisfactory function, ureteral reimplantation into the bladder or ureteroureterostomy (anastomosing the ectopic upper pole ureter into the normally inserting lower pole ureter) is indicated. If function is poor, partial or total nephrectomy is indicated. Often this can be done laparoscopically.

Ureterocele.

A ureterocele is a cystic dilatation of the terminal ureter and is obstructive because of a pinpoint ureteral orifice. Ureteroceles are much more common in females than in males. Affected children often are discovered by prenatal ultrasonography or present with a UTI. Ureteroceles may be ectopic, in which the cystic swelling extends through the bladder neck into the urethra, or orthotopic, in which the ureterocele is entirely within the bladder.

In girls, ureteroceles are nearly always associated with ureteral duplication (Fig. 532–7), whereas in boys there often is only one ureter. The ureter involved with the ureterocele drains the upper renal moiety, which frequently functions poorly or is dysplastic because of congenital obstruction. The lower pole ureter drains into the bladder superior and lateral to the upper pole ureter and frequently refluxes.

Ectopic ureteroceles extend submucosally into the urethra. Rarely, large ectopic ureteroceles may cause bladder outlet obstruction and retention of urine with bilateral hydronephrosis;

Figure 532-7 *A*, Infant with ectopic ureterocele. Sonogram of left kidney shows massive dilatation of the upper pole and a normal lower pole. *B*, VCUG shows large ureterocele, draining the left upper pole, in the bladder. No reflux is present.

in females, the ureterocele may prolapse from the urethral meatus (see Chapter 536). Both simple and ectopic ureteroceles can be bilateral. Ultrasonography is effective in demonstrating the ureterocele and whether the associated obstructed system is duplicated or single. VCUG usually shows a filling defect, sometimes large, in the bladder corresponding to the ureterocele, and often shows reflux into the adjacent

lower pole collecting system with typical findings of a “drooping lily” appearance to the kidney. Renal scintigraphy is most accurate in demonstrating whether the affected renal moiety has significant function.

Treatment of ectopic ureteroceles is variable among different medical centers and depends on whether the upper pole functions on renal scan and whether there is reflux into the lower poleureter. If there is no function of the upper pole and there is no reflux, treatment usually involves laparoscopic or open excision of the obstructed upper pole and most of the associated ureter. If there is function in the upper pole, there is significant reflux; or if the patient is septic from infection of the hydronephrotic kidney, then transurethral incision with cautery or the holmium laser is appropriate initial therapy to decompress the ureterocele. However, reflux into the incised ureterocele is common and subsequent excision of the ureterocele and ureteral reimplantation usually is necessary.

Orthotopic ureteroceles are associated with duplicated or nonduplicated collecting systems, and the orifice is in the expected location in the bladder (Fig. 532–8). They are usually discovered during an investigation for prenatal hydronephrosis or a UTI. Ultrasonography is sensitive for detecting the ureterocele in the bladder and hydroureteronephrosis. IVP reveals varying degrees of ureteral and calyceal dilatation, and there is a round filling defect in the bladder. In delayed films, the cystic dilatation of the ureter may be clearly visible and full of contrast material. Transurethral incision of the ureterocele effectively relieves the obstruction, but it may result in vesicoureteral reflux, necessitating ureteral reimplantation later. Some prefer open excision of the ureterocele and reimplantation as the initial form of treatment. Small, simple ureteroceles incidentally discovered without upper tract dilatation may not require treatment.

Megaureter.

A classification of megaureters (dilated ureter) is given in Table 532–3 . There are numerous disorders that can cause ureteral dilatation, and many are nonobstructive.

Megaureters are usually discovered through screening ultrasonography of the kidneys and bladder because of a prenatal diagnosis of hydronephrosis or postnatal UTI, hematuria, or abdominal pain. A careful history, physical examination, and VCUG identify causes of secondary megaureters and refluxing megaureters as well as the prune-belly syndrome. Primary obstructed megaureters and nonobstructed megaureters probably represent varying severities of the same anomaly.

The primary obstructed nonrefluxing megaureter results from abnormal development of the distal ureter, with collagenous tissue replacing the muscle layer. There is disruption of normal ureteral peristalsis, and the proximal ureter widens. Usually there is not a true stricture. On IVP, the distal ureter is more

TABLE 532-3 -- **Classification of Megaureter**

Refluxing		**Obstructed**		**Nonrefluxing and Nonobstructed**	
Primary	***Secondary***	***Primary***	***Secondary***	***Primary***	***Secondary***

			Postoperative		

Figure 532-8 Simple intravesical ureterocele. Excretory urogram shows left hydronephrosis and a round filling defect on the left side of the bladder corresponding to a simple ureterocele causing left ureteral obstruction. This lesion was treated by transurethral incision and drainage of the ureterocele.

dilated in its distal segment and tapers abruptly at or above the junction of the bladder (Fig. 532–9). The lesion may be unilateral or bilateral. Dilatation of the upper collecting system and calyceal blunting are suggestive of obstruction. Megaureter predisposes to UTI, urinary stones, and flank pain because of urinary stasis. In most cases, diuretic renography and sequential sonographic studies can reliably differentiate obstructed from nonobstructed megaureters. Generally, hydronephrosis lessens and most megaureters diminish in size over time (Fig. 532–10). Truly obstructed megaureters require surgical treatment, with excision of the narrowed segment, ureteral tapering, and reimplantation of the ureter. The results of surgical reconstruction are usually good, but the prognosis depends on pre-existing renal function and whether complications develop.

If differential renal function is normal (>45%) and the child is asymptomatic, it seems safe to follow the patient with serial ultrasonography and diuretic renography to monitor renal function and drainage. These children should receive prophylactic antimicrobial therapy while there is urinary stasis in the

Figure 532-9 Obstructed nonrefluxing megaureter. Excretory urogram in a girl with a history of a febrile urinary tract infection. The right side is normal. The left side reveals hydroureteronephrosis with predominant dilatation of the distal ureter. Note the characteristic appearance of the distal ureter. There was no vesicoureteral reflux. The diagnosis of obstruction was confirmed by diuretic renography.

upper ureter and kidney. If renal function deteriorates, upper urinary tract drainage slows, or UTI occurs, ureteral reimplantation is recommended. Overall, 20–30% of children with a nonrefluxing megaureter undergo ureteral reimplantation.

Prune-Belly Syndrome.

This syndrome, also called *triad syndrome* or *Eagle-Barrett syndrome,* occurs in approximately 1 in 40,000 births; 95% of affected individuals are male. The characteristic association of deficient abdominal muscles, undescended testes, and urinary tract abnormalities probably results from severe urethral obstruction in fetal life (Fig. 532–11). Oligohydramnios and pulmonary hypoplasia are frequent complications in the perinatal period. Many affected infants are stillborn. Urinary tract abnormalities include massive dilatation of the ureters and upper tracts and a very large bladder, with a patent urachus or a urachal diverticulum. Most patients have vesicoureteral reflux. The prostatic urethra is usually dilated, and the prostate is hypoplastic. The anterior urethra may be dilated, resulting in a megalourethra. Rarely, there is urethral stenosis or atresia. The kidneys usually show various degrees of dysplasia, and the testes are usually intra-abdominal. There is often malrotation of the bowel. Cardiac abnormalities occur in 10% of cases; more than 50% have abnormalities of the musculoskeletal system, including limb abnormalities and scoliosis. In females, anomalies of the urethra, uterus, and vagina are usually present.

Many neonates with prune-belly syndrome have difficulty with effective bladder emptying because the bladder musculature is poorly developed and the urethra may be narrowed. When no obstruction is present, the goal of treatment is the prevention of urinary tract infection with antibiotic prophylaxis. When obstruction of the ureters or urethra is demonstrated, temporary drainage procedures, such as a vesicostomy, may help to preserve renal function until the child is old enough for surgery. Some children with prune-belly syndrome have been found to have classic or atypical posterior urethral valves. Urinary tract infections are frequent and should be treated promptly. Correction of the undescended testes by orchidopexy can be difficult in these children because the testes are located high in the abdomen and is best accomplished in the first 6 mo of life. Reconstruction of the abdominal wall offers cosmetic and functional benefits.

Figure 532-10 Neonate with primary nonrefluxing megaureter. *A*, Renal sonogram shows grade IV hydronephrosis. *B*, Dilated ureter. Renal scan showed equal function with the contralateral kidney and satisfactory drainage with diuresis stimulation. *C*, Follow-up sonogram at 10 months shows complete resolution of hydronephrosis.

Figure 532-11 Prune-belly syndrome. Photograph of a 1,600-g newborn with the prune-belly syndrome. Note the lack of tonicity of the abdominal wall and the wrinkled appearance of the skin.

The prognosis ultimately depends on the degree of pulmonary hypoplasia and renal dysplasia. One third of children with prune-belly syndrome are stillborn or die in the first few months of life because of pulmonary complications. Of the long-term survivors, as many as 30% develop end-stage renal disease from dysplasia or complications of infection or reflux and eventually require renal transplantation. The results of renal transplantation in these patients are favorable.

Bladder Neck Obstruction.

Bladder neck obstruction is usually secondary to ectopic ureterocele, bladder calculi, or a tumor of the prostate (rhabdomyosarcoma). The manifestations include difficulty voiding, urinary retention, urinary tract infection, and bladder distention with overflow incontinence. Apparent bladder neck obstruction is common in cases of posterior urethral valves, but it seldom has any functional significance. Primary bladder neck obstruction is extremely rare.

Posterior Urethral Valves.

The most common cause of severe obstructive uropathy in children is posterior urethral valves, affecting 1 in 8,000 boys. Urethral valves refers to tissue leaflets fanning distally from the prostatic urethra to the external urinary sphincter. Typically, the leaflets are separated by a slitlike opening. Valves are of unclear embryologic origin and cause varying degrees of obstruction. Approximately 30% of patients experience end-stage renal disease or chronic renal insufficiency. The prostatic urethra dilates, and the bladder muscle undergoes hypertrophy. Vesicoureteral reflux occurs in 50% of patients, and distal ureteral obstruction may result from a chronically distended bladder or bladder muscle hypertrophy. The renal changes range from mild hydronephrosis to severe renal dysplasia; their severity probably depends on the severity of the obstruction and the time of its onset in fetal life. As in other cases of obstruction or renal dysplasia, there may be oligohydramnios and pulmonary hypoplasia.

Affected boys with posterior urethral valves are discovered prenatally when maternal ultrasonography reveals bilateral hydronephrosis, a distended bladder, and, if the obstruction is severe, oligohydramnios. Prenatal bladder decompression by percutaneous vesicoamniotic shunt or open fetal surgery has been reported. Experimental and clinical evidence of the possible benefits of fetal intervention is lacking, and few affected fetuses are candidates. Prenatally diagnosed posterior urethral valves, particularly when discovered in the second trimester, carry a poorer prognosis than those detected after birth. In the male neonate, posterior urethral valves are suspected when there is a palpably distended bladder and the urinary stream is weak. If the obstruction is severe and goes unrecognized during the neonatal period, infants may present later in life with failure to thrive due to uremia or sepsis caused by infection in the obstructed urinary tract. With lesser degrees of obstruction, children present later in life with difficulty in achieving diurnal urinary continence or with UTI. The diagnosis is established with a VCUG (Fig. 532–12) or by perineal ultrasonography.

After the diagnosis is established, renal function and the anatomy of the upper urinary tract should be carefully evaluated. In the healthy neonate, a small polyethylene feeding tube (No. 5 or 8 French) is inserted in the bladder and left for several days. Passing the feeding tube may be difficult, because the tip of the tube

may coil in the prostatic urethra. A sign of this problem is that urine drains around the catheter rather than through it. A Foley (balloon) catheter should not be used, because the balloon may cause severe bladder spasm, which may produce severe ureteral obstruction.

If the serum creatinine level remains normal or returns to normal, treatment consists of transurethral ablation of the valve leaflets, which is performed endoscopically under general anesthesia. If the urethra is too small for transurethral ablation, temporary vesicostomy is preferred, in which the dome of the bladder is exteriorized on the lower abdominal wall. When the child is older, the valves may be ablated and the vesicostomy closed.

If the serum creatinine level remains high or increases despite bladder drainage by a small catheter, secondary ureteral obstruction, irreversible renal damage, or renal dysplasia should be suspected. In such cases, a vesicostomy should be performed. Cutaneous pyelostomy rarely affords better drainage when compared with cutaneous vesicostomy, and the latter also allows continued bladder growth and gradual improvement in bladder wall compliance.

Infants presenting later in life with uremia without infection should be evaluated and treated after identical guidelines. In the septic and uremic infant, lifesaving measures must include prompt correction of the electrolyte imbalance and control of the infection by appropriate antibiotics. Drainage of the upper tracts by percutaneous nephrostomy and hemodialysis may be necessary. After the patient's condition becomes stable,

Figure 532-12 Posterior urethral valves. Voiding cystourethrogram in an infant with posterior urethral valves. Note the dilatation of the prostatic urethra and the transverse linear filling defect corresponding to the valves.

---

step-by-step evaluation and treatment can be undertaken. Most boys presenting with incontinence can be treated by primary valve ablation.

Favorable prognostic factors include having a normal prenatal ultrasonogram between 18 and 24 wk of gestation, a serum creatinine level less than 0.8 to 1.0?mg/dL after bladder decompression, and visualization of the corticomedullary junction on renal sonography. There are several situations in which a “popoff valve” may occur during urinary tract development, which preserves the integrity of one or both kidneys. For example, 15% of boys with posterior urethral valves have unilateral reflux into a nonfunctioning dysplastic kidney, termed the *VURD syndrome* (valves, unilateral reflux, dysplasia). In these boys, the high bladder pressure is dissipated into the nonfunctioning kidney, allowing normal development of the contralateral kidney. In newborn boys with urinary ascites, the urine generally leaks out from the obstructed collecting system through the renal fornices, allowing normal renal development. Unfavorable prognostic factors include the presence of oligohydramnios in utero, identification of hydronephrosis before 24 wk of gestation, a serum creatinine level greater than 1.0?mg/dL after bladder decompression, identifying cortical cysts in both kidneys, and persistence of diurnal incontinence beyond 5 yr of age.

The prognosis in the newborn is related to the degree of pulmonary hypoplasia and potential for recovery of renal function. Severely affected infants are often stillborn. Of those who survive the neonatal period, approximately 30% retain some degree of renal insufficiency and many eventually require renal transplantation. In some series, renal transplantation in children with posterior urethral valves has a lower success rate than does transplantation in children with normal bladders, presumably because of the adverse influence of altered bladder function on graft function and survival.

After valve ablation, antimicrobial prophylaxis is beneficial in preventing UTI, because hydronephrosis often persists to some degree for many years. These boys should be evaluated annually with a renal ultrasonogram, physical examination, including assessment of somatic growth and blood pressure, urinalysis, and determination of serum levels of electrolytes. Many boys have significant polyuria resulting from a concentrating defect secondary to prolonged obstructive uropathy. If these children acquire a systemic illness with vomiting or diarrhea, or both, urine output cannot be used to assess the child's hydration status. They can become dehydrated quickly, and there should be a low threshold for hospital admission for intravenous rehydration. Some of these patients have renal tubular acidosis, requiring oral bicarbonate therapy. If there is any significant degree of renal dysfunction, growth impairment, or hypertension, they should be followed closely by a pediatric nephrologist. When vesicoureteral reflux is present, expectant treatment and prophylactic doses of antibacterial drugs are advisable. If breakthrough UTI occurs, surgical correction should be undertaken.

After treatment, boys with urethral valves often do not achieve diurnal urinary continence as early as other boys. Incontinence may result from a combination of factors, including uninhibited bladder contractions, poor bladder compliance, bladder atonia, bladder neck dyssynergia, or polyuria. Often these boys need to undergo urodynamic evaluation with urodynamics or videourodynamics to plan therapy. Boys with noncompliance are at significant risk for ongoing renal damage, even in the absence of infection. Using an indwelling catheter overnight has been shown to be beneficial in boys with polyuria. Urinary incontinence usually improves with age, particularly after puberty. Meticulous attention to bladder compliance, emptying, and infection may improve results in the future.

Urethral Atresia.

The most severe form of obstructive uropathy in boys is urethral atresia. In utero there is a distended bladder, bilateral hydroureteronephrosis, and oligohydramnios. In most cases, these infants are stillborn or succumb to pulmonary hypoplasia. Some boys with prune-belly syndrome also have urethral atresia. If the urachus is patent, oligohydramnios is unlikely and the infant usually survives. Urethral reconstruction is difficult, and most patients are managed with continent urinary diversion.

Urethral Hypoplasia.

Urethral hypoplasia is a less severe form of obstructive uropathy than is urethral atresia in boys. In urethral hypoplasia, the urethral lumen is extremely small. This

condition is rare. These neonates typically have bilateral hydronephrosis and a distended bladder. Passage of a small pediatric feeding tube through the urethra is difficult or impossible. Usually a cutaneous vesicostomy must be performed to relieve upper urinary tract obstruction, and the severity of renal insufficiency is variable. The most severely affected boys have end-stage renal disease. Treatment includes urethral reconstruction, gradual urethral dilatation, or continent urinary diversion.

Urethral Strictures.

Urethral strictures *in males* usually result from urethral trauma, either iatrogenic (catheterization, endoscopic procedures, or previous urethral reconstruction) or accidental (straddle injuries or pelvic fractures). Because these lesions may develop gradually, the decrease in force of the urinary stream is seldom noticed by the child or the parents. More commonly, the obstruction causes symptoms of bladder instability, hematuria, or dysuria. Catheterization of the bladder is usually impossible. The diagnosis is made by a voiding film obtained during intravenous urography or retrograde urethrography. Ultrasonography has also been used to diagnose urethral strictures. Endoscopy is confirmatory. Endoscopic treatment of short strictures by dilatation or internal urethrotomy is usually successful. Longer strictures surrounded by periurethral fibrosis often require urethroplasty. Repeated endoscopic procedures should generally be avoided, because they may cause additional urethral damage. Noninvasive measurement of the urinary flow rate and pattern is useful for diagnosis and follow-up.

In females, true urethral strictures are exceptional because the female urethra is protected from trauma, particularly in childhood. In the past it was thought that a distal urethral ring commonly caused obstruction of the female urethra and urinary tract infection and that affected girls benefited from urethral dilatation. The diagnosis was suspected when a “spinning top” deformity of the urethra was found in the VCUG (see Fig. 535–4) and was confirmed by urethral calibration. There is no correlation between the radiologic appearance of the urethra in the VCUG and the urethral caliber and no significant difference in urethral caliber between females with recurrent cystitis and normal age-matched controls. The finding usually is secondary to detrusor-sphincter dyssynergia. Consequently, urethral dilatation in girls is rarely indicated.

Anterior Urethral Valves and Urethral Diverticula in the Male.

Anterior urethral valves are rare. The obstruction is not obstructing valve leaflets, as occurs in the posterior urethra. Rather, it is a urethral diverticulum in the penile urethra that expands during voiding. The distal extension of the diverticulum causes extrinsic compression of the distal penile urethra, causing urethral obstruction. Typically there is a soft mass on the ventral surface of the penis at the penoscrotal junction. In addition, the urinary stream often is weak and the physical findings associated with posterior urethral valves often are present. The diverticulum may be small and minimally obstructive or in other cases may be severely obstructive and cause renal insufficiency. The diagnosis is suspected on physical examination and is confirmed by the VCUG. Treatment involves open excision of the diverticulum or transurethral excision of the distal urethral cusp. *Urethral diverticula* occasionally occur after extensive hypospadias repair.

Fusiform dilatation of the urethra or megalourethra may result from underdevelopment of the corpus spongiosum and support structures of the urethra. This condition is commonly associated with the prune-belly syndrome.

Male Urethral Meatal Stenosis.

Chapter 533 - Anomalies of the Bladder

BLADDER EXSTROPHY

Exstrophy of the urinary bladder occurs about once in every 35,000 to 40,000 births. The male:female ratio is 2:1. The severity ranges from a small vesicocutaneous fistula in the abdominal wall or simple epispadias to complete exstrophy of the cloaca involving exposure of the entire hindgut and the bladder.

Clinical Manifestations.

These anomalies result when the mesoderm fails to invade the cephalad extension of the cloacal membrane; the extent of this failure determines the degree of the anomaly. In classic bladder exstrophy (Fig. 533–1), the bladder protrudes from the abdominal wall and its mucosa is exposed. The umbilicus is displaced downward, the pubic rami are widely separated in the midline, and the rectus muscles are separated. In males, there is complete epispadias with a wide and shallow scrotum. Undescended testes and inguinal hernias are common. Females also have epispadias, with separation of the two sides of the clitoris and wide separation of the labia. The anus is displaced anteriorly in both sexes, and there may be rectal prolapse. Individuals with exstrophy tend to be shorter than normal. The consequences of untreated bladder exstrophy are total urinary incontinence and an increased incidence of bladder cancer, usually adenocarcinoma. The genital deformities can produce sexual disability in both sexes, particularly in the male. The wide separation of the pubic rami causes a characteristic broad-based gait but no significant disability. In classic bladder exstrophy, the upper urinary tracts usually are normal.

Treatment.

Management of bladder exstrophy should start at birth. The bladder should be covered with plastic wrap to keep the bladder mucosa moist. Application of gauze or petroleum-gauze to the bladder mucosa should be avoided. The infant should then be promptly transferred to a center equipped for the treatment of such anomalies. Conventional therapy has included a series of staged reconstructive procedures, but more recently a single-stage complete reconstruction in the neonatal infant is popular.

Prompt closure of the exstrophic bladder is the preferred treatment. During this procedure the abdominal wall is mobilized and the pubic rami are brought together in the midline. If the bladder closure is performed during the first 48?hr of life, there is

sufficient mobility of the pubic rami to allow approximation of the pubic symphysis. If the procedure is delayed, however, the pelvic bone must be broken (pelvic osteotomy) to allow the pubic rami to be brought together. Early bladder closure can be applied to almost all neonatal infants with classic bladder exstrophy. Treatment should be deferred in selected situations when surgery would be excessively risky or complex, such as in a premature baby.

Total reconstruction includes closure of the bladder, closure of the abdominal wall, and, in the male, correction of epispadias using the technique of penile disassembly. Postoperatively, the infant's upper urinary tract is monitored closely for the possible development of hydronephrosis and infection. The majority of such infants have vesicoureteral reflux and should receive antibiotic prophylaxis. In the male, if the epispadias is not corrected at birth, then epispadias repair is generally performed between 1–2 yr of age. At this point the child has total urinary incontinence because there is no external urinary sphincter.

The final stage of reconstruction involves creation of a sphincter muscle for bladder control and correction of the vesicoureteral reflux. In general, the child is at least 3 yr of age, the bladder capacity should be at least 80?mL, and the child must have gained rectal control.

At puberty, the pubic hair is distributed to the sides of the external genitals. A monsplasty is performed to provide a more normal escutcheon.

Prognosis.

This plan of treatment has yielded more than 70% continence in some centers, with less than 15% deterioration of the upper urinary tract. This continence rate reflects not only the successful reconstruction but also the quality and size of the bladder. Children who undergo reconstructive surgery as newborns have a greater chance of obtaining a normally functioning bladder. Children who remain incontinent for more than 1 yr after bladder neck reconstruction or those who are not eligible for bladder neck reconstruction because of a small bladder capacity are candidates for an alternative reconstructive procedure to achieve dryness. Such procedures include (1) augmentation cystoplasty, in which the bladder is enlarged with a patch of small or large bowel to increase its capacity; (2) creation of a neobladder out of small and large bowel with placement of a continent abdominal stoma through which clean intermittent catheterization can be performed; (3) placement of an artificial urinary sphincter, with possible augmentation cystoplasty; and (4) ureterosigmoidostomy, in which the ureters are detached from the bladder and sutured to the sigmoid colon. Individuals with the latter procedure void from the rectum and rely on their anal sphincter for continence. This operation was popular in the past and is still employed in some centers; it is attractive because it avoids the need for external urinary diversion. However, it carries a significant risk of chronic pyelonephritis, upper urinary tract damage, metabolic acidosis resulting from absorption of hydrogen ion and chloride in the intestine, and at least a 15% long-term risk of colonic carcinoma.

Figure 533-1 Classic bladder exstrophy. The bladder is exposed in the midline; the umbilical cord is displaced caudad; the penis is epispadiac; and the scrotum is broad.

Late follow-up has shown that men with exstrophy have a penis that is half normal size but experience satisfactory sexual function. Fertility has been low, possibly because of iatrogenic injury to the secondary sexual organs during reconstruction. In women, fertility is not affected but uterine prolapse during pregnancy is a problem.

OTHER EXSTROPHY ANOMALIES

Children with more complex cases of *cloacal exstrophy,* which has an incidence of 1 in 400,000, have an omphalocele and severe abnormalities of the colon and the rectum and often have short bowel syndrome. Approximately 50% of patients have an upper urinary tract anomaly, and 50% have spina bifida. Current reconstructive techniques result in a satisfactory outcome in most patients with permanent urinary diversion (either ileal conduit or continent urinary diversion) and a colostomy. Because the penis in boys with cloacal exstrophy usually is diminutive, genital reconstruction in males with cloacal exstrophy generally has been unsatisfactory. In the past most specialists recommended assigning a female gender to such infants, but currently there is debate whether these children with a 46,XY karyotype and androgen imprinting in utero can have a satisfactory female gender identity. Decisions regarding gender assignment should be made jointly by the physicians caring for the infant (surgical team, pediatric endocrinologist, child psychiatrist, and ethicist) and family.

Epispadias is in the spectrum of exstrophy anomalies, affecting approximately 1 in 117,000 boys and 1 in 480,000 girls. In boys, the diagnosis is obvious because the prepuce is distributed primarily on the ventral aspect of the penile shaft and the urethral meatus is on the dorsum of the penis. In girls, the clitoris is bifid and the urethra is split dorsally. Distal epispadias in boys usually is associated with normal urinary control and normal upper urinary tracts and should be repaired by 6–12 mo of age. In the more severe cases of epispadias, the sphincter is incompletely formed and these individuals (male and female) have total urinary incontinence and usually separation of the pubic rami. These children require surgical reconstruction procedures analogous to those of the 2nd and 3rd stages of management of patients with classic bladder exstrophy.

BLADDER DIVERTICULA

Bladder diverticula usually occur at the ureterovesical junction and are associated with vesicoureteral reflux (see Fig. 531–6), because the diverticulum interferes with the normal flap-valve attachment between the ureter and bladder. Congenital diverticula occur in other locations also. Bladder diverticula are also commonly associated with distal urethral obstruction or neurogenic bladder dysfunction. Small diverticula require no treatment other than that of the primary disease, whereas large diverticula may contribute to inefficient voiding, residual urine, urinary stasis, and urinary tract infections and should be excised.

URACHAL ANOMALIES

Urachal abnormalities are more common in males than in females. A patent urachus

can occur as an isolated anomaly, or it may be associated with prune-belly syndrome. In this condition there is continuous urinary drainage from the umbilicus. The tract should be excised surgically. Another urachal anomaly is the urachal cyst, which can become infected. Typical symptoms and physical findings include suprapubic pain, fever, irritative voiding symptoms, and an infraumbilical mass, which can be erythematous. Diagnosis is made by ultrasonography or computed tomography. Treatment is intravenous antibiotic therapy and drainage and excision. Other urachal anomalies include the urachal diverticulum, which is a diverticulum of the bladder dome, and external urachal sinus, which is a blind external sinus that opens at the umbilicus. These lesions should be excised.

Chapter 534 - Neuropathic Bladder

Neuropathic bladder dysfunction in children is usually congenital and may result from myelomeningocele, lipomeningocele, sacral agenesis, or other spinal abnormalities. Acquired diseases and traumatic lesions of the spinal cord are less frequent. Central nervous system tumors, sacrococcygeal teratoma, and spinal abnormalities associated with imperforate anus can also result in abnormal innervation of the bladder or sphincter, or both.

Myelodysplasia.

Myelodysplasia *(spina bifida)* describes various abnormal conditions of the vertebral column that affect spinal cord function, including *myelomeningocele* and *meningocele* (see Chapter 585). The incidence of myelodysplasia is 1 in 1,000 births in the United States, but with antenatal screening and abortion, the incidence is decreasing. A few medical centers have been performing selective antenatal myelomeningocele closure, but follow-up studies of the urinary tract have not shown a definite improvement in lower urinary tract function.

The most important consequences of neurogenic bladder dysfunction associated with myelodysplasia are urinary incontinence, urinary tract infections (UTIs), and upper tract deterioration. Hydronephrosis, pyelonephritis, and renal function deterioration are common causes of premature demise of affected individuals.

In the neonate, renal ultrasonography, a random check of postvoid residual urine volumes, and a voiding cystourethrogram are performed after closure of the back. Ten to 15 percent of patients have hydronephrosis and 25% have vesicoureteral reflux. A *urodynamic study* should also be performed. This study involves filling the bladder with saline and measuring the bladder volume and pressure, as well as assessing sphincter tone. During bladder filling, the bladder may show (1) uninhibited (premature) contractions at low volumes, (2) normal bladder volume with contraction at an appropriate volume, or (3) atonia (lack of bladder contraction). Bladder compliance or elasticity may also be reduced. The sphincter may show (1) normal tone with relaxation during bladder contraction, (2) reduced or absent tone, or (3) normal or increased tone that increases during bladder contraction (termed *detrusor-sphincter dyssynergia*) (Fig. 534–1).

Renal damage usually results from failure of the sphincter to relax during a bladder contraction. This dyssynergia results in functional obstruction of the bladder outlet, leading to high intravesical pressure, bladder muscle hypertrophy and trabeculation, and transmission of the high pressure into the upper urinary tract, causing hydronephrosis (Fig. 534–2). Vesicoureteral reflux and urinary tract infection (UTI) compound the problem. Treatment includes reduction of bladder pressure with anticholinergic drugs (oxybutynin, 0.2?mg/kg/24?hr in two or three divided doses) and clean intermittent catheterization every 3–4?hr. If there is vesicoureteral reflux or UTIs, antimicrobial

Figure 534-1 Grouping of neurogenic bladder dysfunction according to the innervation, tonicity, and coordination of the detrusor and sphincters described by Guzman. This grouping is based on data from imaging studies, cystometrography, and electromyography of the sphincters. Patients in group *B* are at risk of developing reflux and hydronephrosis. For guidance in the treatment of incontinence, group *A* benefits from procedures that increase outlet resistance, group *B* from anticholinergics or bladder augmentation surgery, and group *C* from intermittent catheterization and group *D* requires both increased outlet resistance and pharmacologic or surgical bladder enlargement. Most patients require intermittent catheterization to empty. (Modified from Gonzalez R: Urinary incontinence. In Kelalis PK, King LR, Belman AB [editors]: *Clinical Pediatric Urology*. Philadelphia, WB Saunders, 1992, p 387.)

prophylaxis is also prescribed. In the newborn or infant, temporary urinary diversion by cutaneous vesicostomy is a satisfactory alternative for severe reflux. Another option in the child with severe detrusor sphincter dyssynergia is botulinum toxin (Botox) injection into the sphincter. This procedure usually requires general anesthesia and results in sphincteric incompetence for 4–6 mo. Clean intermittent catheterization and anticholinergic therapy cure the reflux in up to 80% of patients without ureteral dilatation (grades I and II). Children with more severe reflux often require corrective surgery followed by intermittent catheterization and anticholinergic drugs. When intermittent catheterization is difficult or if anticholinergic agents are not well tolerated, a temporary cutaneous vesicostomy provides effective bladder decompression. Failure of these methods to relieve intravesical pressures is an indication for augmentation enterocystoplasty and intermittent catheterization.

Urinary incontinence in the child with neuropathic bladder can result from total or partial denervation of the sphincter, bladder hyperreflexia, poor bladder compliance, chronic urinary retention, or a combination of these factors. Less than

Figure 534-2 Voiding cystourethrogram in an infant with myelodysplasia shows a severely trabeculated bladder with multiple diverticula and grade V (out of V) right vesicoureteral reflux. Evaluation showed severe detrusor-sphincter dyssynergia.

5% of children born with myelodysplasia achieve normal continence. Supravesical diversion, commonly performed in the 1970s to prevent incontinence, has a high long-term complication rate and is now seldom employed.

Incontinence often is addressed around 4 yr of age. Nearly all children require clean intermittent catheterization to stay dry. This technique allows efficient bladder emptying with minimal risk of symptomatic UTI. The treatment of incontinence is tailored to the individual case. The urinary tract should be evaluated with renal ultrasonography, a voiding cystourethrogram, and a urodynamic study, including bladder capacity. If the sphincter tone is sufficient and the bladder has adequate compliance, intermittent catheterization every 3–4?hr is usually successful in keeping

the child dry. If there are unstable bladder contractions, an anticholinergic medication such as oxybutynin chloride, hyoscyamine, or tolterodine is prescribed to increase bladder capacity. If there is sphincter incompetence, a-adrenergic medications are prescribed to enhance outlet resistance. Bacteriuria is seen in up to 50% of children using intermittent self-catheterization, but it seldom causes symptoms. In the absence of reflux, there seems to be little cause for concern. Antibacterial prophylaxis can often be effective in keeping the urine sterile while intermittent catheterization is used. With this treatment plan, 40–85% of patients are dry, depending on one's definition of continence. Some children wear a pad in their underwear or a diaper but state that they are dry.

If there is persistent incontinence despite these measures, reconstructive urinary tract surgery usually can provide complete or satisfactory continence. If urethral resistance is low, implantation of an artificial sphincter is usually successful. This sphincter consists of an inflatable cuff that is placed around the bladder neck, a pressure-regulating balloon implanted in the extraperitoneal space, and a pumping mechanism that is implanted in the scrotum of males and in the labia majora of females. Alternatively, bladder neck reconstructive procedures often are successful. If the bladder capacity or bladder compliance is low, or if there are persistent uninhibited contractions despite anticholinergic therapy, enlargement of the bladder with a patch of small or large intestine or stomach, termed **augmentation cystoplasty** or **enterocystoplasty**, is effective. These patients still need to perform clean intermittent catheterization. If urethral catheterization is difficult, a continent stoma may be incorporated into the urinary tract reconstruction. A common method is termed the **Mitrofanoff** procedure, in which the appendix is isolated from the cecum on its vascular pedicle and is interposed between the bladder and abdominal wall to allow intermittent catheterization through a dry stoma. Many of these patients also have bowel problems with constipation, and some benefit from a procedure termed the **Malone antegrade continence enema** procedure, in which the appendix is brought out to the skin to allow a catheter to be inserted into the cecum for antegrade enema.

There are important potential complications of enterocystoplasty:

1. The urine is usually colonized with gram-negative bacteria, and attempts to sterilize the urine for prolonged periods usually fail. There is no evidence that chronic bacteriuria in these patients is associated with renal damage. Therefore, only symptomatic UTIs should be treated.
2. The enteric mucosal surface in contact with the urine absorbs ammonium, chloride, and hydrogen ions and loses potassium. Hyperchloremic metabolic acidosis can result and may require medical treatment (see Chapter 45). Chronic acidosis may compromise skeletal growth. This complication is more common in patients with compromised renal function. To overcome this limitation of enterocystoplasty in patients with chronic renal insufficiency, a gastric segment can be used instead of a segment of the small or large intestine. The stomach secretes chloride and hydrogen ions; thus, pre-existing metabolic acidosis remains stable or improves. However, the possibility of intractable metabolic alkalosis and peptic ulceration of the augmentation has diminished the enthusiasm for this procedure. Composite augmentations using stomach and small or large bowel has resulted in few metabolic complications.
3. Perforation of the augmented bladder and peritonitis are serious complications that are potentially life-threatening. This complication seems to result from acute or chronic overdistention of the augmented bladder. These patients typically present with severe abdominal pain. Prompt diagnosis and treatment with exploratory laparotomy and bladder closure are necessary. Meticulous adherence to the prescribed program of intermittent catheterization to avoid bladder overdistention is important.
4. Bladder calculi have developed in as many as 70% of children followed for 10 yr after enterocystoplasty. The calculi develop because of mucus that accumulates in the bladder and acts as a nidus for stone formation.
5. The potential for malignancy secondary to enterocystoplasty is unknown, but, based on past experience with ureterosigmoidostomy and some reported cases, it is prudent to advise yearly endoscopic examinations or urine cytologic studies beginning in the 10th postoperative year.

Latex Allergy.

One of the most serious problems encountered by as many as half of individuals with spina bifida and other urologic conditions that require clean intermittent catheterization and urinary tract reconstructive procedures is latex allergy. This IgE-mediated allergy is acquired and is secondary to repeated exposure to the medically associated latex allergen. Latex allergy may manifest as watery eyes, sneezing, itching, hives, or anaphylaxis when blowing up a balloon or if an examiner is

---

using latex gloves. Intraoperatively, a sensitized individual can experience anaphylactic shock. A latex-free environment should be provided for these children in the office, during hospitalization, and during operative procedures.

Occult Spinal Dysraphism.

Approximately 1 in 4,000 patients have occult spinal dysraphism, which includes lipomeningocele, intradural lipoma, diastematomyelia, tight filum terminale, dermoid cyst-sinus, aberrant nerve roots, anterior sacral meningocele, and cauda equina tumor. More than 90% of patients have a cutaneous abnormality overlying the lower spine, including a small dimple, tuft of hair, dermal vascular malformation, or a subcutaneous lipoma (Fig. 534–3). Often these children have high arched feet, discrepancy in muscle size and strength between the legs, and a gait abnormality. Newborns and young infants usually have a normal neurologic examination. Older children often have absent perineal sensation and back pain. Lower urinary tract function is abnormal in 40% of patients, including incontinence, recurrent UTI, and fecal soiling. The likelihood of a normal examination is inversely related to the age at surgical correction of the spinal lesion. In infants with abnormal urodynamics, 60% revert to normal; in older children only 27% become normal. Management of the urinary tract in other children is similar to that described for myelodysplasia.

Sacral Agenesis.

Sacral agenesis is defined as the absence of part or all of two or more lower

vertebral bodies. This condition is more common in the offspring of women with diabetes. These children have flattened buttocks and a low, short gluteal cleft but usually have no orthopedic deformity, although some have high arched feet. Palpation of the coccygeal area reveals the absent vertebrae. Approximately 20% of cases are undetected until the age of 3–4 yr; many are diagnosed after unsuccessful toilet training. Urodynamic studies in these children show a variety of patterns, and most need clean intermittent catheterization and pharmacotherapy to stay dry.

Imperforate Anus.

Between 30% and 45% of children with a high imperforate anus have a neuropathic bladder, often because of

Figure 534-3 Buttocks of teenage boy with tethered cord secondary to lipomeningocele. Note sacral dimple and deviation of gluteal fold to the left.

sacral agenesis. Newborns with imperforate anus should undergo a spinal ultrasound during their initial evaluation; and if these children have difficulty with toilet training, complete urologic evaluation with upper and lower urinary tract imaging and urodynamics should be performed. (Also see Chapter 325 .)

Cerebral Palsy.

Children with cerebral palsy have reasonable bladder control. However, continence is achieved at a later age than in unaffected children. Their upper urinary tracts are usually normal. Urodynamic studies have shown that most have uninhibited bladder contractions. Timed voiding and anticholinergic therapy is usually effective. Clean intermittent catheterization rarely is necessary. (Also see Chapters 37 and 591.1 .)

Chapter 535 - Voiding Dysfunction

NORMAL VOIDING AND TOILET TRAINING

In the fetus, voiding occurs by reflex bladder contraction and is “balanced,” with simultaneous contraction of the bladder and relaxation of the sphincter. Urine storage consists of sympathetic and pudendal nerve–mediated inhibition of detrusor contractile activity accompanied by closure of the bladder neck and proximal urethra with increased activity of the external sphincter.

The infant has coordinated, reflex voiding as often as 15 to 20 times per day. Over time, the bladder enlarges gradually, and the average *bladder capacity* in ounces is equal to the age (in years) plus 2. This formula applies to children up to the age of 12–14 yr. At 2–4 yr, toilet training begins. To achieve normal conscious bladder control, several steps must occur: (1) awareness of bladder filling, (2) cortical inhibition (suprapontine modulation) of reflex (unstable) bladder contractions, (3) ability to consciously tighten the external sphincter to prevent incontinence, (4) normal bladder growth, and (5) motivation by the child to stay dry. The *transitional phase of voiding* refers to the period when children are acquiring bladder control. Girls typically acquire bladder control before boys, and bowel control is typically achieved before urinary control. By 5 yr of age, 90–95% are nearly completely continent during the day and 80–85% are continent at night (also see Chapter 20).

NOCTURNAL ENURESIS (See Chapter 20.3)

Nocturnal enuresis is the occurrence of involuntary voiding at night at 5 yr, the age when volitional control of micturition is expected. Enuresis may be primary (75%; nocturnal urinary control never achieved) or secondary (25%; the child was dry at night for at least a few months and then enuresis occurs). In addition, 75% of children with enuresis are wet only at night, whereas 25% are wet day and night. This distinction is important because the pathogenesis of the two patterns is different.

Epidemiology.

Approximately 60% of children with nocturnal enuresis are boys. Family history is also important and is positive in 50% of cases. Although primary nocturnal enuresis may be polygenetic, candidate genes have been localized to chromosomes 12 and 13. If one parent was enuretic, each child has a 44% risk of enuresis; if both parents were enuretic, each child has a 77% likelihood of enuresis. Nocturnal enuresis without overt daytime voiding symptoms affects up to 20% of children at the age of 5 yr; it ceases spontaneously in approximately 15% of involved children every year thereafter. Its frequency among adults is less than 1%.

Pathogenesis.

The pathogenesis of primary nocturnal enuresis (normal daytime voiding habits) is multifactorial and includes the following:

- Delayed maturation of the cortical mechanisms that allow voluntary control of the micturition reflex.
- Sleep disorder–enuretic children, who are classically described as being deep sleepers, although no specific sleep pattern has been described. Enuresis can occur in any stage of sleep. All children are most difficult to arouse in the first third of the night and are easiest to awaken in the last third of the night, but enuretic children are more difficult to arouse than those with normal bladder control.
- Reduced antidiuretic hormone production at night, resulting in an increased urine output, which explains why children with enuresis often are described as “soaking the bed.”
- Genetic factors, with chromosomes 12 and 13q the likely sites of the gene for enuresis; family history is often positive in enuretic children, as described earlier.
- Psychologic factors, often implicated in secondary enuresis.
- Organic factors, such as urinary tract infection (UTI) or obstructive uropathy, which is an uncommon cause of enuresis.
- Sleep apnea (snoring) secondary to enlarged adenoids.

Clinical Manifestations and Diagnosis.

A careful history should be obtained, especially with respect to fluid intake at night and pattern of nocturnal enuresis. Children with diabetes insipidus, diabetes mellitus, and chronic renal disease may have a high obligatory urinary output and a compensatory polydipsia. The family should be asked whether the child snores loudly at night. A complete physical examination should include palpation of the abdomen and rectal examination after voiding to assess the possibility of a chronically distended bladder. The child with nocturnal enuresis should be examined carefully for neurologic and spinal abnormalities. There is an increased incidence of bacteriuria in enuretic girls, and, if found, it should be investigated and treated (see Chapter 530), although this does not always lead to resolution of bed-wetting. Urinalysis should be obtained after an overnight fast and evaluated for specific gravity or osmolality, or both, to exclude polyuria as a cause of frequency and incontinence and to ascertain that the concentrating ability is normal. The absence of glycosuria should be confirmed. If there are no daytime symptoms and if the physical examination and urinalysis are normal, and culture is negative, further evaluation for urinary tract pathology generally is not warranted. A renal ultrasonogram is reasonable in an older child with enuresis or in children who do not respond appropriately to therapy.

Treatment.

The best approach to treatment is to reassure parents that the condition is self-limited and to avoid punitive measures that may affect the child's psychologic development adversely (see Chapter 20.3). Fluid intake should be restricted to 2?oz after 6 or 7 o'clock in the evening if the child weighs less than 75?lb, 3?oz if the child weighs 75 to 100?lb, and 4?oz if the child weighs more than 100?lb. In addition, the parents should be certain that the child voids at bedtime. If the child snores and the adenoids are enlarged, referral to an otolaryngologist should be considered, because adenoidectomy may result in cure of the enuresis.

Active treatment should be avoided in children younger than age 6 yr because enuresis is extremely common in younger children. The simplest initial measure is motivational and includes a star chart for dry nights. Waking children a few hours after they go to sleep to have them void often allows them to awaken dry, although this measure is not curative. Some have recommended that children try holding their urine for longer periods during the day, but there is no evidence that this approach is beneficial. *Conditioning therapy* involves use of an auditory alarm attached to electrodes in the underwear. The alarm sounds when voiding occurs and is intended to awaken children and alert them to void. This form of therapy is considered curative and has a reported success of 30–60%. Often the alarm wakes up other family members and not the enuretic child; persistence for several months is necessary. A vibratory alarm is available also. Conditioning therapy tends to be most effective in older children. Another form of therapy to which some children respond is *self-hypnosis*. The primary role of psychological therapy is to help the child deal with enuresis psychologically and help motivate arising to void at night if the child awakens with a full bladder.

Pharmacologic therapy is intended to treat the symptom of enuresis and is not curative. One form of treatment is *desmopressin acetate*, which is a synthetic analog of antidiuretic hormone and reduces urine production overnight. It is available as a tablet, with a dosage of 0.2–0.6?mg at bedtime. In the past it was used as a nasal spray, with a dosage of 10?µg (1 spray) to 40?µg (4 sprays total) at bedtime. The lowest effective dose should be used. It is important to reduce evening fluid intake, and the drug should not be used if the child has a systemic illness with vomiting or diarrhea. Hyponatremia has been reported in a few children using the nasal spray, primarily those who were not using the medication properly. It has not been reported in children using the tablets. In children with rhinorrhea, the nasal spray is not absorbed and consequently is ineffective. Desmopressin acetate is effective in as many as 40% of children. If effective, it should be used for 3–6 mo, and then an attempt should be made to taper it. If tapering results in recurrent enuresis, the medication may be started again at the higher dosage. No adverse events have been reported with the long-term use of desmopressin acetate. Another pharmacologic agent is *imipramine*, which is a tricyclic antidepressant. This medication has mild anticholinergic and a-adrenergic effects and may alter the sleep pattern also. The dosage of imipramine is 25?mg in children age 6–8 yr, 50?mg in children age 9–12 yr, and 75?mg in teenagers. Reported success rates are 30–60%. Side effects include anxiety, insomnia, and dry mouth. In addition, the drug is one of the most common causes of poisoning by prescription medication in younger siblings. Oxybutynin chloride, a pure anticholinergic agent, has been used in some children with primary nocturnal enuresis, but the response rate is low.

DIURNAL INCONTINENCE

Daytime incontinence not secondary to neurologic abnormalities is common in children. At age 5 yr, 95% have been dry during the day at some time and 92% are dry. At 7 yr, 96% are dry, although 15% have significant urgency at times. At 12 yr, 99% are dry during the day. The most common cause of daytime

---

incontinence is a pediatric unstable bladder (also termed *uninhibited or overactive bladder, bladder spasms*). Table 535–1 lists the causes of diurnal incontinence in children.

Important points in the history include the pattern of incontinence, including the frequency, the volume of urine lost during incontinent episodes, whether the incontinence is associated with urgency or giggling, whether it occurs after voiding, and whether the incontinence is continuous. In addition, the frequency of voiding and whether there is nocturnal enuresis, a strong, continuous urinary stream, or sensation of incomplete bladder emptying should be assessed. Other urologic problems such as UTIs, reflux, neurologic disorders, or a family history of duplication anomalies should be assessed. Bowel habits also should be evaluated, because incontinence is common in children with constipation or encopresis, or both. Diurnal incontinence may occur in girls with a history of sexual abuse. Physical examination is directed at identifying signs of organic causes of incontinence: short stature, hypertension, enlarged kidneys or bladder or both, constipation, labial adhesion, ureteral ectopy (Figs. 535–1 to 535–3), back or sacral anomalies (see Fig. 534–3), and neurologic abnormalities. A urinalysis or culture, or both, should be performed to check for infection. In some cases, assessing the postvoid residual urine volume or urinary flow rate is appropriate. Imaging is reserved for children who have significant physical findings, a family history of urinary tract anomalies, UTIs, or those who do not respond to therapy appropriately. A renal ultrasonogram with or without a voiding cystourethrogram is indicated. Urodynamics may be helpful if there is evidence of neurologic disease or if empirical therapy is ineffective.

PEDIATRIC UNSTABLE (OVERACTIVE) BLADDER

A pediatric unstable bladder is smaller than normal and exhibits strong uninhibited contractions. These children typically exhibit urinary frequency, urgency, and urge incontinence. Such symptoms are also seen in about 25% of children with nocturnal enuresis. Often girls will squat down on their foot to try to prevent incontinence (“Vincent curtsy”). Many children indicate they do not feel the need to urinate, even just before they are incontinent. In females, a history of recurrent UTI is common, but incontinence may persist long after infections are brought under control. It is not clear in these cases if the voiding dysfunction is a sequel of the infections or if the voiding dysfunction predisposes to recurrent infections. In girls, voiding cystourethrography (VCUG) often shows a dilated urethra (“spinning top deformity”; Fig. 535–4) and narrowed bladder neck with bladder wall hypertrophy. The urethral finding results from inadequate relaxation of the external urinary sphincter. In

addition, constipation is common.

Initial therapy is timed voiding every 1.5–2?hr and anticholinergic therapy with oxybutynin chloride, hyoscyamine, or

TABLE 535-1 -- **Causes of Urinary Incontinence in Childhood**

Combination

Figure 535-1 Duplication of the right collecting system with ectopic ureter. Excretory urogram in a female presenting with a normal voiding pattern and constant urinary dribbling. The left kidney is normal, and the right side, well visualized, is the lower collecting system of a duplicated kidney. On the upper pole opposite the first and second vertebral bodies, note the accumulation of contrast material corresponding with a poorly functioning upper pole drained by a ureter opening in the vestibule.

tolterodine. Constipation and UTIs also must be addressed. This treatment program is usually prolonged and should be interrupted periodically to determine its continued need. An alternative to pharmacologic therapy is biofeedback, in which children are taught pelvic floor exercises, because there is evidence that daily performance of these exercises may reduce or eliminate

Figure 535-2 Ectopic ureter. The photograph shows an ectopic ureter entering the vestibule next to the urethral meatus. The thin ureteral catheter with transverse marks has been introduced into this ectopic ureter. This girl had a normal voiding pattern and constant urinary dribbling.

unstable bladder contractions. In some children treatment with an alpha blocker such as terazosin or doxazosin may aid in timed voiding. Children not responding to therapy should be evaluated endoscopically and urodynamically to rule out other possible forms of bladder or sphincter dysfunction.

NON-NEUROGENIC NEUROGENIC BLADDER (HINMAN SYNDROME)

Hinman syndrome is a more serious but less common disorder involving failure of the external sphincter to relax during voiding in children without neurologic abnormalities. Children with this syndrome, also called *detrusor-sphincter dyssynergia,* typically exhibit a staccato stream, day and night wetting, recurrent UTIs, constipation, and encopresis. Evaluation of affected children often reveals vesicoureteral reflux, a trabeculated bladder, and a decreased urinary flow rate with an intermittent pattern. In severe cases, hydronephrosis, renal insufficiency, and even end-stage renal disease can occur. The pathogenesis of this syndrome is thought to involve learning abnormal voiding habits during toilet training; the syndrome is rarely seen in infants. Urodynamic studies and magnetic resonance imaging of the spine are indicated to rule out a neurologic cause for the bladder dysfunction. The treatment is usually complex and may include anticholinergic and alpha blocker therapy, timed voiding, treatment of constipation, behavioral modification, and encouragement of relaxation during voiding. Biofeedback has been used successfully in older children to teach relaxation of the external sphincter. In some cases botulinum toxin (Botox) injection into the external sphincter can provide temporary sphincteric paralysis and thereby reduce outlet resistance. In severe cases, intermittent catheterization is necessary to ensure bladder emptying. In selected patients, external urinary diversion is necessary to protect the upper urinary tract. These children require long-term treatment and careful follow-up.

INFREQUENT VOIDING

Infrequent voiding is a common disorder of micturition, usually associated with urinary tract infections. Affected children, usually girls, void only twice a day rather than the normal four to seven times. With bladder overdistention and prolonged retention of urine, growth of bacteria can lead to recurrent UTIs. Some of these children are constipated. Some also have occasional episodes of incontinence due to overflow or urgency. The disorder is behavioral. When the children have UTIs, the treatment is antibacterial prophylaxis and encouragement of frequent voiding and complete emptying of the bladder by double voiding until a normal pattern of micturition is re-established.

VAGINAL VOIDING

In girls with vaginal voiding, incontinence typically occurs after urination after the girl stands up. Usually the volume of urine is 5–10?mL. One of the most common causes is *labial adhesion* (see Fig. 535–3). This lesion is seen in young girls and can be managed either by topical application of estrogen cream to the adhesion or lysis in the office. Some girls experience vaginal voiding because they do not separate their legs widely during urination. These girls are usually overweight or do not pull their underwear down to their ankles when they urinate. Management involves encouragement of the girl to separate the legs as widely as possible during urination. The most effective way to do this is to have the child sit backward on the toilet seat during micturition.

OTHER CAUSES OF INCONTINENCE IN GIRLS

Ureteral ectopia, usually associated with a duplicated collecting system in girls, can produce urinary incontinence characterized by constant dribbling of urine during day and night, even though they void regularly. Sometimes the urine production from the renal segment drained by the ectopic ureter is small and urinary drainage is confused with watery vaginal discharge.

Figure 535-4 Spinning top deformity. VCUG demonstrating dilation of the urethra with distal urethral narrowing and contraction of the bladder neck.

Children with a history of vaginal discharge or incontinence and an abnormal voiding pattern require careful study. The ectopic orifice is usually difficult to find. On ultrasonography or intravenous urography, one may suspect duplication of the collecting system (see Fig. 535–1), but the upper collecting system drained by the ectopic ureter usually has poor or delayed function. Computed tomography of the kidneys helps rule out subtle duplication that may not be discovered on intravenous urography. Examination under anesthesia for an ectopic ureteral orifice in the vestibule or the vagina is often necessary (see Fig. 535–2). The treatment in these cases is either partial nephrectomy, with removal of the upper pole segment of the duplicated kidney and its ureter down to the pelvic brim, or ipsilateral ureteroureterostomy, in which the upper pole ectopic ureter is anastomosed to the normally positioned lower pole ureter.

Giggle incontinence is a condition that typically affects girls between 7 and 15 yr of age. The incontinence occurs suddenly during giggling, and the entire bladder volume is lost. The pathogenesis is thought to be sudden relaxation of the urinary sphincter. Anticholinergic medication and timed voiding rarely are effective. The most effective treatment is methylphenidate administration.

Total incontinence may be secondary to *epispadias*. This condition, which affects only 1 of 480,000 females, is characterized by separation of the pubic symphysis, separation of the right and left sides of the clitoris, and a patulous urethra. Treatment is bladder neck reconstruction to repair the totally incompetent urethra.

A short, incompetent urethra may be associated with certain urogenital sinus malformations. The diagnosis of these malformations requires a high index of suspicion and a careful physical examination of all incontinent girls. In these cases, urethral and vaginal reconstruction can often restore continence.

VOIDING DISORDERS WITHOUT INCONTINENCE

Some children have the abrupt onset of severe urinary frequency, voiding as often as every 10–15?min during the day, without dysuria, UTI, daytime incontinence, or nocturia. The most common age for these symptoms to occur is 4–6 yr, after the child is toilet-trained, and the vast majority are boys. This condition is termed the *daytime frequency syndrome of childhood* or *pollakiuria*. The condition is functional; no anatomic problem is detected. Often the symptoms occur just before a child starts kindergarten or if the child is having emotional family stress–related problems. These children should be checked for UTI, and the clinician should ascertain that the child is emptying the bladder satisfactorily. Occasionally, pinworms can cause these symptoms. The condition is self-limited, and symptoms generally resolve within 2–3 mo. Anticholinergic therapy rarely is effective.

Some children have the *dysuria-hematuria syndrome*, in which the child has dysuria without UTI and microscopic or gross hematuria. This condition affects children who are toilet-trained and often is secondary to hypercalciuria. A 24-hr urine sample should be obtained and calcium and creatinine excretion assessed. A 24-hr calcium excretion of more than 4?mg/kg is abnormal and deserves treatment with thiazides because some of these children may be at risk for urolithiasis.

Chapter 536 - Anomalies of the Penis and Urethra

Hypospadias.

Hypospadias refers to a urethral opening that is on the ventral surface of the penile shaft and affects 1 in 250 male newborns. There is incomplete development of the prepuce, termed a *dorsal hood,* in which the foreskin is on the sides and dorsal aspect of the penile shaft and absent ventrally. Some boys, particularly those with proximal hypospadias, have chordee, in which there is ventral penile curvature during erection. The incidence of hypospadias may be increasing, possibly because of in utero exposure to estrogenic or antiandrogenic endocrine-disrupting chemicals (polychlorbiphenyls, phytoestrogens).

CLINICAL MANIFESTATIONS.

Hypospadias is classified according to the position of the urethral meatus after taking into account whether chordee is present (Fig. 536–1). The deformity is described as glanular (on the glans penis), coronal, subcoronal, midpenile, penoscrotal, scrotal, and perineal. Approximately 60% of cases are distal, 25% are subcoronal or midpenile, and

Figure 536-1 Subcoronal hypospadias. Note the urethral meatus in the subcoronal position and the incomplete or hooded prepuce. There was no ventral curvature of the penis in this case.

15% are proximal. In the more severe cases, the scrotum is bifid and sometimes extends to the dorsal base of the penis (scrotal engulfment) (Fig. 536–2). There is also a *megameatal variant,* in which the foreskin is normally developed, but there is either distal or subcoronal hypospadias with a “fish mouth” meatus (Fig. 536–3). These cases may not be diagnosed until after a circumcision is performed.

Hypospadias usually is an isolated anomaly. However, hypospadias is common in boys with multiple congenital anomalies. Approximately 10% of boys with hypospadias have an undescended testis, and inguinal hernias are also common. In the newborn, the differential diagnosis of proximal hypospadias with an undescended testis should include forms of ambiguous genitalia, particularly masculinization of females (congenital adrenal hyperplasia) and mixed gonadal dysgenesis. A karyotype should be obtained in patients with midpenile or proximal hypospadias and

cryptorchidism (see Chapter 577). Boys with penoscrotal hypospadias should undergo a voiding cystourethrogram because 5–10% have a dilated prostatic utricle, which is a remnant of the müllerian system. The incidence of other anomalies of the genitourinary tract in boys with hypospadias is low, and with the exception of the more severe cases of perineal hypospadias, radiographic studies of the urinary tract are unnecessary.

Complications of untreated hypospadias include (1) deformity of the urinary stream, either ventral deflection or severe splaying; (2) sexual dysfunction secondary to penile curvature; (3) infertility if the urethral meatus is proximal; and (4) meatal stenosis (congenital), which is extremely rare. The goal of hypospadias surgery is to correct the functional and cosmetic deformities. Whereas hypospadias repair is recommended for boys with midpenile and proximal hypospadias, some boys with distal hypospadias will have no functional abnormality and do not need any surgical correction.

TREATMENT.

Management begins in the newborn period. Circumcision should be avoided, because the foreskin is often used in the repair. The ideal age for repair in a healthy infant is 6–12 mo. This age is chosen because (1) there is no greater risk of general anesthesia at this age than at 2–3 yr, (2) penile growth over the next several years is slow, (3) the child does not remember the surgical procedure, and (4) analgesic needs are less than in older children. Nearly all cases are repaired in a single operation on an outpatient basis. In most boys with distal

Figure 536-2 Severe perineoscrotal hypospadias. Note the ventral curvature and the underdeveloped ventral surface of the penis, the hooded prepuce, and the urethral meatus in the mid-line of the bifid scrotum. This child had palpable gonads and a normal chromosome pattern.

hypospadias the urethral plate is tubularized, whereas with more proximal cases a vascularized skin flap from the foreskin is used and the remaining foreskin covers the ventral penile surface. The complication rate is low: less than 5% for distal hypospadias, 5–10% for midpenile hypospadias, and 15% for proximal hypospadias. Complications include urethrocutaneous fistula, hematoma, wound infection, meatal stenosis, urethral diverticulum, and wound dehiscence. Repair of hypospadias is a technically demanding operation and should be performed by surgeons with special training and extensive experience.

Chordee without Hypospadias.

In some boys there is ventral penile curvature (chordee) and incomplete development of the foreskin (dorsal hood), but the urethral meatus is at the tip of the glans. In most of these boys, the urethra is normal but there is insufficient ventral penile skin or prominent, inelastic ventral bands of dartos fascia that prevent a normal straight erection. In some cases, however, the urethra is short and hypoplastic, and a formal urethroplasty is necessary for repair. The only sign of this anomaly in the neonate may be the dorsal hood deformity, and delayed repair under general anesthesia at 6 mo of age is recommended.

Phimosis and Paraphimosis.

Phimosis refers to the inability to retract the prepuce. At birth, phimosis is physiologic. Over time the adhesions between the prepuce and glans lyse and the distal phimotic ring loosens. In 90% of uncircumcised males the prepuce becomes retractable by the age of 3 yr. Accumulation of epithelial debris under the infantile prepuce is not pathologic and does not require surgical treatment. In older boys, phimosis may be physiologic, may be pathologic from inflammation and scarring at the tip of the foreskin, or may occur after circumcision (see later discussion of trapped penis). The prepuce may have been retracted forcefully on one or two occasions in the past, which can result in a cicatricial scar that prevents subsequent foreskin retraction. In boys with persistent physiologic or pathologic phimosis, application of corticosteroid cream to the foreskin three times daily for 1 mo loosens the phimotic ring in

---

two thirds of cases. If there is ballooning of the foreskin during voiding or phimosis beyond 10 yr of age, circumcision is recommended.

Paraphimosis occurs when the foreskin is retracted behind the coronal sulcus and the prepuce cannot be pulled back over the glans (Fig. 536–4). Painful venous stasis in the retracted foreskin results, with edema leading to severe pain and inability to reduce the foreskin (pull it back over the glans). Treatment includes lubrication of the foreskin and glans and then compressing the glans and simultaneously placing distal traction on the foreskin to try to push the phimotic ring beyond the coronal sulcus. In rare cases, emergency circumcision under general anesthesia is necessary.

Circumcision.

Whether the newborn male should undergo circumcision is controversial. In the United States, circumcision is usually performed for social reasons. Reasons given in support of circumcision include reducing the risk of urinary tract infection (UTI) and sexually transmitted diseases and prevention of penile cancer, phimosis, and balanitis.

UTIs are 10 to 15 times more common in uncircumcised infants than in circumcised infants, the urinary pathogens arising from bacteria that colonize the space between the prepuce and glans. The risk of febrile UTI is primarily between birth and 6 mo, but there is an increased risk of UTI at least through 5 yr of age. Many recommend circumcision in infants who are predisposed to UTI, such as those with congenital hydronephrosis and vesicoureteral reflux. Whether circumcision reduces the risk of sexually transmitted diseases, in particular acquired immunodeficiency syndrome, is unresolved, because most of the data have been acquired from countries in which the prevalence of acquired immunodeficiency syndrome is high and because it has

been difficult to ascertain whether the sexual practices of the circumcised and uncircumcised subjects were similar. There have been only a handful of reports of adult men who were circumcised at birth and subsequently acquired penile carcinoma, but in Scandinavian countries, where few men are circumcised and hygiene is good, the incidence of penile cancer is low.

Complications after neonatal circumcision include bleeding, wound infection, meatal stenosis, secondary phimosis, removal of insufficient foreskin, and dense penile adhesions (skin bridge; Fig. 536–5); 0.2–3% of patients have a subsequent operative procedure. Boys with a large hydrocele or hernia are at particular risk for secondary phimosis (see later discussion of trapped penis). Potentially serious complications include sepsis,

Figure 536-4 Paraphimosis. Foreskin has been retracted proximal to the glans penis and has become markedly swollen secondary to venous congestion.

Figure 536-5 Skin bridges between glans and penile shaft resulting from penile adhesions forming after newborn circum-cision. Skin bridges cause painful penile curvature during erection and predispose to infection under the adhesion and should be excised.

amputation of the distal part of the glans, removal of an excessive amount of foreskin, and urethrocutaneous fistula. Circumcision should not be performed in neonates with hypospadias, chordee without hypospadias, or a dorsal hood deformity (relative contraindication) or in those with a small penis.

When performing a neonatal circumcision, local analgesia, such as a dorsal nerve block or application of EMLA cream, is recommended.

Penile Torsion.

Penile torsion is a rotational defect of the penile shaft. It usually occurs in a counterclockwise direction, that is, to the left side. In most cases, penile development is normal and the condition is unrecognized until circumcision is performed or the foreskin is retractable. Penile torsion also occurs in some boys with hypospadias. The defect has primarily cosmetic significance and correction is unnecessary if the rotation is less than 60 degrees from the midline.

Inconspicuous Penis.

The term *inconspicuous penis* refers to a penis that appears to be small. A *webbed penis* is a condition in which the scrotal skin extends onto the ventrum of the penis. This deformity represents an abnormality of the attachment between the penis and scrotum. Although the cosmetic appearance is only mildly abnormal, if a routine circumcision is performed, the penis tends to retract into the scrotum and can result in secondary phimosis. In rare cases, the distal urethra is hypoplastic, necessitating urethral reconstruction. The *concealed (hidden or buried) penis* is a normally developed penis that is camouflaged by the suprapubic fat pad (Fig. 536–6). This anomaly may be congenital or iatrogenic after circumcision. A *trapped penis* is an acquired form of inconspicuous penis and refers to a phallus that becomes embedded in the suprapubic fat pad after circumcision (Fig. 536–7). This deformity may occur after neonatal circumcision in an infant who has significant scrotal swelling from a large hydrocele or inguinal hernia or after routine circumcision in an infant with a webbed penis. This complication can predispose to UTIs and may cause urinary retention.

Figure 536-6 Concealed penis (*A*), which may be visualized by retracting skin lateral to penile shaft (*B*).

Micropenis.

Micropenis is defined as a normally formed penis that is at least 2.5 standard deviations below the mean in size (Fig. 536–8). Typically, the ratio of the length of the penile shaft to its circumference is normal. The pertinent measurement is the *stretched penile length*, which is measured by gently stretching the penis and measuring the distance from the penile base under the pubic symphysis to the tip of the glans. The mean length of a newborn penis is 3.5 ± 0.7?cm and 1.1 ± 0.2?cm in diameter, and it should be at least 1.9?cm in length. Micropenis results from a hormonal abnormality that occurs after 14 wk of gestation. Common causes include (1) hypogonadotropic hypogonadism, (2) hypergonadotropic hypogonadism (primary testicular failure), and (3) idiopathic micropenis. The most common cause of micropenis is failure of the hypothalamus to produce an adequate amount of gonadotropin-releasing hormone, and typically this occurs in Kallmann syndrome, Prader-Willi syndrome, and Lawrence-Moon-Biedl syndrome. In some cases, there is

Figure 536-7 Concealed, trapped penis secondary to circumcision. This baby's penis is normal length; large hydroceles predisposed him to this complication.

Figure 536-8 Infant with microphallus. Also note the small scrotum, which was empty.

growth hormone deficiency. Primary testicular failure may result from gonadal dysgenesis or rudimentary testes syndrome and also occurs in Robinow syndrome. All these children should be examined by a pediatric endocrinologist and pediatric urologist. Evaluation includes a karyotype, assessment of anterior pituitary function, testicular function, and magnetic resonance imaging to determine the anatomic integrity of the hypothalamus and the anterior pituitary gland as well as the midline structure of the brain. One of the difficult questions is whether androgen therapy is essential during childhood because stimulation of penile growth in a prepubertal boy may limit the growth potential of the penis in puberty. In addition, studies of small numbers of men with micropenis suggest that many, although not all, have satisfactory sexual function. Consequently, a decision for gender reassignment is made infrequently.

Other Penile Anomalies.

Agenesis of the penis affects approximately 1 in 10 million boys. The karyotype is

almost always 46,XY, and the usual appearance is that of a well-developed scrotum with descended testes and an absent penile shaft. Upper urinary tract abnormalities are common. In most cases, gender reassignment is recommended in the newborn period. *Diphallia* ranges from a small accessory penis to complete duplication. *Lateral penile curvature* usually is caused by overgrowth or hypoplasia of a corporal (erectile) body and usually is congenital. Surgical repair is recommended at age 6–12 mo.

Meatal Stenosis.

Meatal stenosis is a condition that is almost always acquired and occurs after neonatal circumcision. It probably results from severe inflammation of the denuded glans. If the meatus is pinpoint, boys void with a forceful, fine stream that goes a great distance. These boys may experience dysuria, frequency, or hematuria, or a combination of these conditions, without UTI between the ages of 3 and 8 yr. Other boys have dorsal deflection of the urinary stream. Although the meatus may be small, hydronephrosis or voiding difficulty is extremely rare unless there is associated balanitis xerotica obliterans. Treatment is meatoplasty, in which the urethral meatus is opened surgically; this procedure can be performed either under anesthesia as an outpatient or in the office using local anesthesia (EMLA cream) with or without sedation. Routine cystoscopy is unnecessary.

Other Male Urethral Anomalies.

Parameatal urethral cyst presents as an asymptomatic small cyst on one side of the urethral meatus. Treatment is excision under anesthesia. *Congenital*

Figure 536-9 Urethral prolapse in a 4-yr-old black girl who had bloody spotting on her underwear.

urethral fistula is a rare deformity in which a fistula is present from the penile urethra. It is usually an isolated abnormality. Treatment is fistula closure. *Megalourethra* is a large urethra that is usually associated with abnormal development of the corpus spongiosum. This condition is most commonly associated with prune-belly syndrome. *Urethral duplication* is a rare condition in which the two urethral channels lie in the same sagittal plane, and the more normal urethra is the one positioned more ventrally. Some children have significant obstructive uropathy and require major reconstructive surgery. *Urethral hypoplasia* is a rare condition in which the urethra is extremely small but patent. In some cases, a temporary cutaneous vesicostomy is necessary for satisfactory urinary drainage. Either gradual enlargement of the urethra or major urethroplasty is necessary.

Figure 536-10 Paraurethral cyst in a newborn girl.

Figure 536-11 Prolapsed ectopic ureterocele in a female infant. She had a nonfunctioning upper pole collecting system connected to the ureterocele.

Urethral atresia refers to nondevelopment of the urethra and is nearly always fatal unless the urachus remains patent throughout gestation.

Urethral Prolapse (Female).

Urethral prolapse is encountered predominantly in black females between 1 and 9 yr of age. The most common signs are bloody spotting on the underwear or diaper, although dysuria or perineal discomfort may also occur (Fig. 536–9). An inexperienced examiner may mistake the finding for sexual abuse. The usual therapy consists of application of estrogen cream two to three times daily for 3–4 wk and sitz baths. Surgical excision and reapproximation of the mucosal edges is curative.

Other Female Urethral Lesions.

Paraurethral cyst results from retained secretions in the Skene glands secondary to ductal obstruction (Fig. 536–10). These lesions are present at birth and most regress in size during the first 4–8 wk, although occasionally it is necessary to incise them. A *prolapsed ectopic ureterocele* appears as a cystic mass protruding from the urethra and is a presenting symptom in 10% of girls with a ureterocele, which is a cystic swelling of the terminal ureter (Fig. 536–11). Ultrasonography should be performed to visualize the upper urinary tracts to confirm the diagnosis. Usually the ureterocele is either incised or an upper urinary tract reconstructive procedure is necessary.

Chapter 537 - Disorders and Anomalies of the Scrotal Contents

UNDESCENDED TESTES

Failure to find one or both testes in the scrotum may indicate that the testis is undescended, absent, or retractile.

Epidemiology.

An undescended (cryptorchid) testis is the most common disorder of sexual differentiation in boys. At birth, approximately 4.5% of boys have an undescended testis. Because testicular descent occurs late in gestation, 30% of premature male infants have an undescended testis; the incidence is 3.4% at term. The majority of undescended testes descend spontaneously during the first 3 mo of life, and by 6 mo the incidence decreases to 0.8%. If the testis has not descended by 6 mo, it will remain undescended. Cryptorchidism is bilateral in 10% of cases. There is some evidence that the incidence of cryptorchidism is increasing. Some boys have secondary cryptorchidism after repair of an inguinal hernia. This complication of hernia repair is most common in neonates and young infants and affects as many as 1–2% of patients.

Pathogenesis.

The process of testicular descent is regulated by an interaction between hormonal and mechanical factors, including testosterone, dihydrotestosterone, müllerian-inhibiting factor, the gubernaculum, intra-abdominal pressure, and the genitofemoral nerve. The testis develops at 7–8 wk of gestation. At 10–11 wk, the Leydig cells produce testosterone, which stimulates differentiation of the wolffian (mesonephric) duct into the epididymis, vas deferens, seminal vesicle, and ejaculatory duct. At 32–36 wk, the testis, which is anchored at the internal inguinal ring by the gubernaculum, begins its process of descent. The gubernaculum distends the inguinal canal and guides the testis into the scrotum.

Clinical Manifestations.

Undescended testes are usually in the inguinal canal. Some boys have an ectopic testis, typically in the superficial inguinal pouch or perineum. Some testes are intra-abdominal; these are nonpalpable. Approximately 10% of cryptorchid boys have a nonpalpable testis; in these the testis is present and abdominal or inguinal in 50%,

and it is absent secondary to perinatal testicular torsion in 50%. In a newborn with bilateral nonpalpable testes, one should suspect that the child could be a virilized female with congenital adrenal hyperplasia.

The consequences of cryptorchidism include infertility, malignancy, associated hernia, torsion of the cryptorchid testis, and the possible psychologic effects of an empty scrotum.

The undescended testis is histologically normal at birth, but pathologic changes can be demonstrated at 6–12 mo. Delayed germ cell maturation, reduction in germ cell number, hyalinization of the seminiferous tubules, and reduced Leydig cell number are typical; these changes are progressive over time if the testis remains undescended. Similar, although less severe, changes are found in the contralateral descended testis after 4–7 yr. After treatment for bilateral undescended testes, 50–65% of patients are fertile; 85% of boys treated for a unilateral undescended testis are fertile.

The risk of *malignancy* in the undescended testis is 4 to 10 times higher than that in the general population and is approximately 1 in 80 with a unilateral undescended testis and 1 in 40 to 1 in 50 for bilateral undescended testes. The peak age for this tumor is 15–45 yr. The most common tumor developing in an undescended testis is a seminoma (65%); in contrast, after orchiopexy, seminomas represent only 30% of testis tumors. Orchiopexy does not change the risk of developing cancer of the testis.

Indirect inguinal hernias usually accompany undescended testes but are rarely symptomatic. *Torsion and infarction* of the undescended testes can occur because of excessive mobility of such testes.

"Acquired" or *ascending undescended testes* are becoming recognized more frequently. These boys have a descended testis at birth, but during childhood, often between 4–10 yr of age, the testis does not remain in the scrotum. In such boys, on physical examination the testis often can be pulled into the scrotum, but there is obvious tension on the spermatic cord. This condition is thought to result from incomplete disappearance of the processus vaginalis so that the spermatic cord does not grow as rapidly as the child, resulting in the testis gradually moving out of a scrotal position.

Retractile testes often are misdiagnosed as undescended testes. Boys older than 1 yr of age frequently have a brisk cremasteric reflex; and if the child is anxious or ticklish during scrotal examination, the testis may be difficult to manipulate into the scrotum. Boys should be examined with their legs in a relaxed frog-leg position, and if the testis can be manipulated into the scrotum comfortably, it is probably retractile. It should be monitored every 6–12 mo with follow-up physical examinations, because it could be an acquired undescended testis. Boys with a retractile testis are not at increased risk for infertility or malignancy.

Treatment.

The undescended testis should be treated at 9–15 mo. Most testes can be brought down to the scrotum with an operation *(orchiopexy).* This procedure involves an inguinal incision, mobilization of the testis and spermatic cord, and correction of the indirect inguinal hernia. The procedure is typically performed on an outpatient basis with a success rate of 98%.

If the testis is *nonpalpable*, diagnostic laparoscopy is performed to determine its location. Ultrasound has been demonstrated to be ineffective in localizing the nonpalpable testis. Approximately 50% of these boys have an intra-abdominal testis or a testis that is located high in the inguinal canal; in the remaining patients, the testis is absent. When the testis is *absent*, usually an atrophic remnant is found in the scrotum or inguinal canal. The atrophy is thought to result from testicular torsion in utero. These gonads have been termed **vanishing testes**. In the majority of cases, orchiopexy of the intra-abdominal testis located immediately inside the internal inguinal ring is successful, but orchiectomy should be considered in the more difficult cases or when the testis appears to be atrophic. Two-stage orchidopexy is sometimes needed in high abdominal testes. Testicular prostheses are available for older children and adolescents when the absence of the gonad in the scrotum may have an undesirable psychologic effect.

Hormonal treatment is used infrequently. The concept is that because testicular descent is under androgen regulation human chorionic gonadotropin (which stimulates Leydig cell production of testosterone) or luteinizing hormone–releasing hormone (LHRH) may stimulate testicular descent. Although hormonal treatment has been used in Europe, randomized controlled trials have not shown either hormone to be very effective. There is

---

some preliminary evidence that an LHRH analog, buserelin, may be helpful in increasing germ cell number and normalizing testicular histologic features.

SCROTAL SWELLING

Scrotal swelling may be acute or chronic and painful or painless. Abrupt onset of painful scrotal swelling necessitates prompt evaluation, because some conditions, such as testicular torsion and incarcerated inguinal hernia, require emergency surgical management. The differential diagnosis is shown in Tables 537–1 and 537–2 .

Clinical Manifestations.

A detailed history is helpful in determining the cause of the swelling and includes (1) onset of pain—with testicular torsion the pain often is sudden in onset and may be associated with exercise or minor genital trauma; (2) duration of pain; (3) radiation of pain—inguinal discomfort is common with an inguinal hernia or epididymitis and associated flank pain may occur with passage of a ureteral calculus; (4) previous episodes of similar pain, which are common in boys with intermittent testicular torsion or inguinal hernia; (5) nausea and vomiting, which are associated with testicular torsion and inguinal hernia; and (6) irritative urinary symptoms, such as dysuria, urgency, and frequency, which are indicative of a urinary tract infection that

can cause epididymitis. Boys with lower urinary tract pathology may be prone to epididymitis.

Physical examination in boys with a painful scrotum may be difficult. Some have advocated performing a spermatic cord block or administering intravenous analgesia to facilitate the examination, but such measures are usually unnecessary. Scrotal wall erythema is common in testicular torsion, epididymitis, torsion of the appendix testis, and an incarcerated hernia. In boys with a normal cremasteric reflex, testicular torsion is unlikely. Absence of a cremasteric reflex, however, is nondiagnostic.

Laboratory Findings and Diagnosis.

Pertinent laboratory studies include a urinalysis and culture. A positive urinalysis is suggestive of epididymitis. Serum studies generally are not helpful in establishing a diagnosis, unless a testis tumor is suspected. After initial evaluation, *imaging studies* may be helpful in establishing the diagnosis. These studies include color Doppler ultrasonography and radionuclide testicular flow scan. Imaging studies are used to assess whether testicular blood flow is normal, reduced, or increased. In addition, if a hydrocele is present and the testis is nonpalpable, or if an abnormality of the testis is found, ultrasonography may be helpful. Imaging studies are not 100% accurate; they should not be used to decide whether a boy with testicular pain should be referred for urologic care.

Color Doppler ultrasonography allows assessment of testicular blood flow and testicular morphologic features. Accuracy is 95% if the ultrasonographer is experienced. A false-negative study (i.e., demonstrates excellent testicular blood flow) may occur in a boy with testicular torsion if the degree of torsion is less than 360 degrees and the duration of torsion is short, because there may be continued testicular perfusion. In addition,

TABLE 537-1 -- **Differential Diagnosis of Scrotal Masses in Boys and Adolescents**

Painful	Painless
Testicular torsion	Hydrocele

Inguinal hernia (incarcerated)*	Meconium peritonitis
Testicular torsion*	Epididymitis*

Occasionally associated with discomfort.

in prepubertal boys blood flow may be difficult to demonstrate in as many as 30% of normal testes.

The ^{99m} Tc-pertechnetate *testicular flow scan* can demonstrate whether there is blood flow to the testis. After intravenous injection of the radionuclide, flow and static images are obtained. Testicular torsion usually appears as a “cold spot” of absent flow to the affected testis. Inflammatory conditions usually cause hyperemia. Accuracy in demonstrating blood flow is approximately 95%. A false-negative scan may occur in a boy with testicular torsion if the degree of torsion is less than 360 degrees. The test can often be obtained on an emergent basis during the day, but at night it may take 2–3?hr to perform and interpret the study.

TESTICULAR (SPERMATIC CORD) TORSION

Testicular torsion requires prompt diagnosis and treatment to save the testis. Torsion is the most common cause of testicular pain in boys 12 yr and older and is uncommon in those younger than 10 yr. It is caused by inadequate fixation of the testis within the scrotum resulting from a redundant tunica vaginalis, allowing excessive mobility of the testis. The abnormal attachment has been termed a **bell clapper deformity** and is often bilateral. Shortly after torsion occurs, venous congestion begins; subsequently, arterial flow is interrupted. The likelihood of testis survival depends on the duration and severity of torsion. Within 4 to 6?hr of absent blood flow to the testis, spermatogenesis may be lost.

Testicular torsion produces acute pain and swelling of the scrotum. On examination, the scrotum is swollen, tender, and often difficult to examine. The cremasteric reflex is nearly always absent. The condition can be differentiated from an incarcerated hernia because swelling in the inguinal area is often absent. If the pain has lasted less than 4–6?hr, manual detorsion may be attempted. This maneuver is performed by rotating the testis outward (the left testis is rotated clockwise). Successful manual detorsion results in dramatic pain relief.

Treatment is prompt surgical exploration and detorsion. If the testis is explored within 6?hr of torsion, as many as 90% of the gonads will survive. Survival decreases rapidly with a delay of more than 6?hr. If the degree of torsion is 360 degrees or less, the testis may have sufficient arterial flow to allow the gonad to survive, even after 24–48?hr. The testis is then fixed in the scrotum with nonabsorbable sutures, termed **scrotal orchiopexy,** to prevent torsion in the future. The contralateral testis should be fixed in the scrotum because the condition may be bilateral. If the testis appears nonviable, orchiectomy is performed (Fig. 537–1).

Testicular torsion can also occur in the fetus or neonate and results from incomplete attachment of the tunica vaginalis to the scrotal wall and is "extravaginal." When torsion occurs in utero, the baby is usually born with a large, firm, nontender testis. Usually the ipsilateral hemiscrotum is ecchymotic (Fig. 537–2). In these cases, the testis is rarely viable because torsion was a remote event. However, the contralateral testis is at increased risk for torsion until 1 mo beyond term. Many pediatric urologists recommend exploration to establish the diagnosis, remove the necrotic testis, and anchor the contralateral testis. In other cases, the initial examination is normal, and

Figure 537-1 Left testicular torsion in an adolescent; the testis is necrotic.

acute scrotal swelling is recognized subsequently. In such cases, the testis occasionally may be saved.

TORSION OF THE APPENDIX TESTIS

Torsion of the appendix testis is the most common cause of testicular pain in boys between 2 and 11 yr but is rare in adolescents. The appendix testis is a stalklike structure that is a vestigial embryonic remnant of the müllerian (paramesonephric) ductal system that is attached to the upper pole of the testis. When it undergoes torsion, progressive inflammation and swelling of the testis and epididymis occurs, resulting in testicular pain and scrotal erythema. The onset of pain is usually gradual. Palpation of the testis usually reveals a 3–5?mm tender indurated mass on the upper pole (Fig. 537–3). In some cases, the appendage that has undergone torsion may be visible through the scrotal skin, termed the *blue dot sign*. In some boys,

Figure 537-2 Left testicular torsion in a newborn. Left hemiscrotum is ecchymotic, and the testis was slightly enlarged, quite firm, and nontender.

Figure 537-3 Torsion of the appendix testis, which is necrotic (*arrow*).

distinguishing torsion of the appendix from testicular torsion is difficult. In such cases, a testicular flow scan or color Doppler ultrasonography may be helpful.

The natural history of torsion of the appendix testis is for the inflammation to resolve in 3–10 days. Nonoperative treatment is recommended, including bed rest and analgesia with nonsteroidal anti-inflammatory medication for 5 days. If the diagnosis is uncertain, scrotal exploration is recommended.

EPIDIDYMITIS

Acute inflammation of the epididymis is an ascending retrograde infection from the urethra, through the vas into the epididymis. This condition causes acute scrotal pain and swelling. It is rare before puberty and should raise the question of a congenital abnormality of the wolffian duct, such as an ectopic ureter entering the vas. After puberty, epididymitis becomes progressively more common and is the principal cause of acute painful scrotal swelling in young, sexually active adult men. Urinalysis usually reveals pyuria. Epididymitis can be infectious (usually gonococcus, *Chlamydia*), but often the organism remains undetermined. Treatment consists of bed rest and antibiotics. Differentiation from torsion can be difficult, and in children surgical exploration is usually required.

VARICOCELE

A varicocele is an abnormal dilatation of the pampiniform plexus in the scrotum (Fig. 537–4). Dilatation of the pampiniform venous plexus results from valvular incompetence of the spermatic vein. Approximately 15% of adult men have a varicocele; 15% are subfertile. Varicocele is the most common surgically correctable cause of subfertility in men. A varicocele is found in 5% of adolescent boys, but it is rare in boys younger than 10 yr old. Varicoceles occur predominantly on the left side, are bilateral in 10% of cases, and rarely involve the right side only. A varicocele in a boy younger than 10 yr or one on the right side may be indicative of an abdominal or retroperitoneal mass; an ultrasonographic scan should be performed.

A varicocele usually is a painless paratesticular mass, often described as a "bag of worms." Occasionally patients describe a dull ache in the affected testis. Usually the varicocele is decompressed when the patient is supine and prominent when standing. Testicular size should be documented because if the affected testis is small, spermatogenesis probably has been adversely affected.

Figure 537-4 Left varicocele in an adolescent boy.

The goal of varicocelectomy is to maximize chances for fertility. Surgical treatment of varicoceles in children and adolescents is indicated in boys with a significant disparity in testicular size or pain in the affected testis, or if the contralateral testis is diseased or absent. Typically the involved testis enlarges and catches up with the normal testis over the following 1–2 yr. Varicocelectomy should also be considered in boys with a large varicocele, even without a disparity in testicular size. Surgical repair is performed by ligation of the veins of the pampiniform plexus through an inguinal incision or by ligating the internal spermatic vein in the retroperitoneum. The

operation is carried out on an ambulatory basis.

SPERMATOCELE

A spermatocele is a cystic lesion containing sperm that is attached to the upper pole of the sexually mature testis. Spermatoceles are usually painless and are incidental findings on physical examination. Enlargement of the spermatocele or pain is an indication for removal.

HYDROCELE

A hydrocele is an accumulation of fluid in the tunica vaginalis (Fig. 537–5). One to 2% of male neonates have a hydrocele. In most cases, the hydrocele is noncommunicating (the processus vaginalis was obliterated during development). In such cases, the hydrocele fluid disappears by 1 yr of age. If there is a persistently patent processus, the hydrocele persists and becomes progressively larger during the day and is small in the morning. A rare variant of a hydrocele is the *abdominoscrotal hydrocele*, in which there is a large, tense hydrocele that extends into the lower abdominal cavity. In some older boys, a noncommunicating hydrocele may result from an inflammatory condition within the

Figure 537-5 Newborn with large right hydrocele.

scrotum, such as testicular torsion, torsion of the appendix testis, epididymitis, or testicular tumor. The risk of a communicating hydrocele is the development of an inguinal hernia.

On examination, hydroceles are smooth and nontender. Transillumination of the scrotum confirms the fluid-filled nature of the mass. If compression of the fluid-filled mass completely reduces the size of the hydrocele, an inguinal hernia is the likely diagnosis.

Most hydroceles resolve by 12 mo of age after reabsorption of the hydrocele fluid. If the hydrocele is large and tense, however, early surgical correction is recommended because it is difficult to verify that the child does not have a hernia, and large hydroceles rarely disappear spontaneously. Hydroceles persisting beyond 12–18 mo are usually communicating and should be repaired. Surgical correction is similar to a herniorrhaphy (see Chapter 327). Through an inguinal incision, the spermatic cord is identified, the hydrocele fluid is drained, and a high ligation of the processus vaginalis is performed.

INGUINAL HERNIA

This condition is similar to hydrocele and is discussed in Chapter 327 .

TESTICULAR TUMOR

Testicular and paratesticular tumors can occur at any age, including in the newborn. Approximately 65% are malignant; most commonly they are yoke sac tumors. Most present as a painless, hard testicular mass that does not transilluminate. Scrotal ultrasonography should be performed to confirm the finding of a testicular mass and may help to delineate the type of testis tumor. Serum tumor markers, a-fetoprotein and ß-human chorionic gonadotropin, should be determined. Definitive therapy includes surgical exploration through an inguinal incision. In most cases a radical orchiectomy, consisting of removal of the entire testis and spermatic cord, is performed, but if the ultrasonographic study or surgical exploration suggests that the tumor is benign, such as a teratoma or epidermoid cyst, removal of the mass only may be performed.

Chapter 538 - Trauma to the Genitourinary Tract

Injuries to the genitourinary tract in children usually result from blunt trauma during falls, athletic activities, or motor vehicle accidents. In more than half of the cases there are also major injuries to the brain, spinal cord, skeleton, lungs, or abdominal organs. Children are at greater risk of blunt renal injury than are adults because of less body fat and because the kidneys are not located directly behind the ribs. Children with a pre-existing renal anomaly such as hydronephrosis secondary to a ureteropelvic junction obstruction, horseshoe kidney, or renal ectopia are also at increased risk for renal injury. Blunt abdominal or flank trauma often causes a renal injury. Falling may cause a deceleration injury that results in an injury to the renal pedicle, interrupting blood flow to the kidney. If the bladder is full, blunt lower abdominal trauma may cause a bladder rupture. Rupture of the membranous urethra occurs in 30% of cases of pelvic fractures. Straddle injuries are usually associated with trauma to the bulbous urethra. Symptoms and signs of urinary tract injury include gross or microscopic hematuria, bleeding from the urethral meatus, abdominal or flank pain, a flank mass, fractured lower ribs or lumbar transverse processes, and a perineal or scrotal hematoma.

Evaluation of the patient begins after an adequate airway has been established and the patient is hemodynamically stable (see Chapter 57). With significant abdominal injury, gross hematuria or more than 50 red blood cells per high-power field, or suspicion of renal injury (e.g., deceleration injury, flank pain or bruise), renal imaging is indicated. In addition, the bladder should be catheterized, unless blood is dripping from the urethral meatus, which is an indication of potential urethral injury. Passing the catheter in the presence of a urethral injury may increase the extent of the damage and convert a partial membranous urethral tear into a total disruption. In these patients, a retrograde urethrogram should be performed by injecting radiopaque contrast medium into the urethral meatus. Oblique radiographs demonstrate the extent of the injury and whether urethral continuity is preserved or has been disrupted.

Spiral computed tomography is performed to evaluate the kidneys, ureters, and bladder. Delayed images are important to detect renal extravasation of blood or urine. Prompt function of both kidneys without extravasation usually excludes significant renal injury. Renal injuries are classified as minor and major. Minor renal injuries are most common and include contusion of the renal parenchyma and shallow cortical lacerations not involving the collecting system. Major renal injuries include deep lacerations involving the collecting system, the shattered kidney, and renal pedicle injuries (Fig. 538–1). Complete absence of function of one kidney without contralateral compensatory hypertrophy (indicative of congenital absence) should be regarded as an indication of major injury to the renal pedicle. Renal angiography, once used to evaluate renal injuries further, particularly if a renal

pedicle injury is suspected, is now rarely used because such patients are often hemodynamically unstable, and management is not significantly affected by the findings. In some cases, a pre-existing renal anomaly may be demonstrated on the study. A ruptured ureteropelvic junction obstruction may be apparent if the kidney is intact but the distal ureter is not visualized.

Minor renal injuries such as contusions are managed by bed rest and monitoring of vital signs until abdominal or flank discomfort and gross hematuria has resolved. Children with a *major renal injury* are usually admitted to an intensive care unit for continuous monitoring of vital signs and urine output. Intravenous antibiotics are also administered. These injuries are also managed nonoperatively, because Gerota fascia often causes tamponade of bleeding from the kidney and dramatic healing of the injured parenchyma can occur even with significant urinary extravasation. Approximately 10% of children with a major renal injury undergo surgical exploration because of hemodynamic instability, persistent extravasation, or persistent hematuria or to correct a congenital renal deformity. It can be difficult to identify normal and devitalized parenchyma, and the likelihood of having to perform a nephrectomy is significant. If the child is undergoing exploration for other abdominal injuries, the injured kidney is examined. If there is persistent extravasation because of intermittent ureteral obstruction from a blood clot, passage of a temporary double-**J** stent endoscopically between the bladder and kidney may allow resolution. If there is a renal pedicle injury, nephrectomy is necessary. The kidney can be salvaged by emergency renal revascularization only if the kidney is explored within 2–3?hr of the injury. All penetrating injuries of the kidneys should be explored. In addition to loss of renal function, the main long-term complication of renal injury is renin-mediated hypertension. Children who sustain renal injuries must have periodic measurement of blood pressure.

Ureteral injuries are usually iatrogenic. Injuries of the ureter by blunt or penetrating trauma require immediate surgical attention.

When the bladder can be catheterized, a static cystogram is obtained, infusing a contrast solution through the catheter by gravity, ideally using fluoroscopy. Flat and oblique views are often obtained; a postvoid film also should be obtained because, in some cases, extravasation may be hidden by the full bladder.

Bladder ruptures can be intraperitoneal or extraperitoneal. All intraperitoneal ruptures require surgical repair. Minor extraperitoneal near-ruptures might be treated by catheter drainage but generally require surgical treatment.

Treatment of a **membranous urethral injury** is controversial. Erectile dysfunction, urethral stricture, and urinary

Figure 538-1 CT scan of girl who sustained major renal injury from falling off a bicycle demonstrates ruptured right kidney with urinary extravasation.

incontinence are the major late complications of rupture of the membranous urethra, and therapy is directed at minimizing the risk of these problems. There is often a large pelvic hematoma with tamponade, and attempting to repair the injury immediately can be technically difficult and result in significant hemorrhage. Many such injuries are initially managed by temporary suprapubic cystostomy, with continuous bladder drainage for 3–6 mo. Subsequently, open or endoscopic urethroplasty can be performed. Alternatively, some try to achieve urethral continuity under anesthesia and leave a urethral catheter for several months. These patients typically require subsequent open or endoscopic urethroplasty.

Penile injury is uncommon. Some boys who are in the process of toilet training sustain an injury to the glans penis if the lid of the toilet falls while they are urinating. These boys often have a hematoma covering the distal half of the glans. Typically, they have no difficulty urinating and do not need extensive evaluation. Adolescent boys who indulge in extremely vigorous sexual intercourse may sustain rupture of one of the corporal bodies. These boys have severe swelling of the penile shaft and require emergency exploration and repair. Boys with penetrating injuries of the penis also require emergency débridement and repair.

Testicular injuries are relatively uncommon in children because of the small size of the testes and their mobility within the scrotum. Such injuries usually result from blunt trauma during athletic activity. Typically, these boys have significant scrotal swelling, testicular pain, and tenderness. Ultrasonography demonstrates rupture of the tunica albuginea, which is the capsule of the testis, and surrounding hemorrhage. Prompt surgical treatment of testicular injuries increases the salvage rate.

Chapter 539 - Urinary Lithiasis

Urinary lithiasis in children is less common in the United States than in other parts of the world. The wide geographic variation in the incidence of lithiasis in childhood is related to climatic, dietary, and socioeconomic factors. Approximately 7% of urinary calculi occur in children younger than 16 yr of age. In the United States, most children with stone disease have a metabolic abnormality. The exceptions are patients with a neuropathic bladder, who are prone to infection-initiated renal stones, and those who have urinary tract reconstruction with intestine, which predisposes to bladder calculi. Metabolic stones are twice as common in boys as in girls and are rare in African-Americans. In Southeast Asia, urinary calculi are endemic and are related to dietary factors.

Stone Formation.

The composition and site of urinary calculi vary, depending on the pathogenesis. Most stones are composed of calcium, oxalate, uric acid, cystine, ammonium, or phosphate crystals, or a combination of these substances (Box 539–1). The risk of stone formation is increased with increasing concentrations of these crystals and reduced with increasing concentrations of inhibitors. Renal calculi develop from crystals that form on the calyx and aggregate to form a calculus. Bladder calculi may be stones that formed in the kidney and traveled down the ureter, or they may form primarily in the bladder.

Stone formation depends on four factors. *Matrix* is a mixture of protein, non-amino sugars, glucosamine, water, and organic ash. Matrix makes up 2–9% of the dry weight of urinary stones and is arranged within the stones in organized concentric laminations. *Precipitation-crystallization* refers to supersaturation of the urine with specific ions comprising the crystal. Once a nucleus of crystal forms, the crystals aggregate by chemical and electrical forces. Increasing the saturation of urine with respect to the ions increases the rate of nucleation, crystal growth, and aggregation and increases the likelihood of stone formation and growth. *Epitaxy* refers to the aggregation of crystals of different composition but similar lattice structure, thus forming stones of a heterogeneous nature. The lattice structures of calcium oxalate and monosodium urate have similar structures, and calcium oxalate crystals can aggregate on a nucleus of monosodium urate crystals. Urine also contains *inhibitors* of

INDINAVIR STONES

NEPHROCALCINOSIS

stone formation, including citrate, diphosphonate, and magnesium ion.

Clinical Manifestations.

Children with urolithiasis usually have gross or microscopic hematuria. If the calculus is in the renal pelvis, calyx, or ureter and causes obstruction, then abdominal or flank pain (renal colic) occurs. Typically the pain radiates anteriorly to the scrotum or labia. Often the pain is intermittent, corresponding to periods of obstruction of urine flow, which increases the pressure in the collecting system. If the calculus is in the distal ureter, the child may have irritative symptoms of dysuria, urgency, and frequency. If the stone has passed into the bladder, the child is usually asymptomatic. If the stone is in the urethra, dysuria and difficulty voiding may result. Some children pass small

amounts of gravel-like material.

Diagnosis.

Approximately 90% of urinary calculi are calcified to some degree and consequently are radiopaque on a plain abdominal film. Some calculi are only a few millimeters in diameter and may not be obvious, particularly if they are in the ureter. Struvite (magnesium ammonium phosphate) stones are radiopaque. Cystine and uric acid calculi may be radiolucent but often are slightly opacified. Some children have **nephrocalcinosis**, which is calcification of the renal tissue itself. Nephrocalcinosis is seen most commonly in premature neonates receiving furosemide, which causes hypercalciuria, and in children with medullary sponge kidney.

In a child with suspected renal colic, a *nonenhanced spiral CT scan of the abdomen and pelvis* is performed in many centers. This study takes only a few minutes to perform, delineates the number and location of calculi, and demonstrates whether the involved kidney is hydronephrotic. In the past, an excretory urogram generally was performed. This test demonstrates a delay in visualization of the collecting system compared with the normal side; and if there is a ureteral calculus, there is columnization of contrast medium down to the stone. If the calculus is radiolucent or small, the urogram may not demonstrate the stone. Consequently, the noncontrast spiral CT scan is preferred. Another alternative is to obtain a plain radiograph of the abdomen and pelvis plus a renal ultrasonogram. If a small calculus is in the ureter, it may not be imaged by these two studies; and if the calculus is not causing impaired urinary flow at the time of the study, the renal ultrasonogram may not show hydronephrosis. In a child with a calculus that already has been diagnosed, however, serial plain films or renal ultrasonography can be used to follow the status of the calculus, such as whether it has grown or diminished in size or moved. If a child has a renal pelvic calculus, a ureteropelvic junction obstruction should be suspected. In some cases, it can be difficult to determine whether hydronephrosis in such a child is secondary to an obstructing stone or the ureteropelvic junction obstruction, or both. Finally, even though a ureteral or renal pelvic stone may be obstructive, a MAG-3 diuretic renogram has no role in assessing whether the stone itself is causing significant obstruction.

Any material that resembles a calculus should be sent for analysis by a laboratory that specializes in the identification of the components of urinary calculi.

METABOLIC EVALUATION.

A metabolic evaluation for the most common predisposing factors should be undertaken in all children with urolithiasis, bearing in mind that structural, infectious, and metabolic factors often coexist. This evaluation should not be undertaken in a child who is in the process of passing a stone because the altered diet and hydration status, as well as the effect of obstruction on the kidney, may alter the results of the study. The basic laboratory studies required are listed in Box 539–2 , and the normal values for 24-hr urine collections are shown in Table 539–1 . In children with hypercalciuria, further studies of calcium excretion with dietary calcium restriction and calcium loading are necessary.

Pathogenesis of Specific Renal Calculi

CALCIUM OXALATE AND CALCIUM PHOSPHATE CALCULI.

Most urinary calculi in children in the United States are composed of calcium oxalate or calcium phosphate, or both. The most common metabolic abnormality in these individuals is hypercalciuria. Between 30–60% of children with calcium stones have hypercalciuria without hypercalcemia. Other metabolic aberrations that predispose to stone disease include hyperoxaluria, hyperuricosuria, hypocitruria, heterozygous cystinuria, hypomagnesuria, hyperparathyroidism, and renal tubular acidosis.

Hypercalciuria may be absorptive, renal, or resorptive. The primary disturbance in **absorptive hypercalciuria** is intestinal hyperabsorption of calcium. In some children, an increase in 1,25-dihydroxyvitamin D is associated with the increased calcium absorption, and in others the process is independent of vitamin D. **Renal hypercalciuria** refers to impaired renal tubular reabsorption of calcium. Renal leak of calcium causes mild hypocalcemia, which triggers an increased production of parathyroid hormone, with increased intestinal absorption of calcium and increased mobilization of calcium stores. **Resorptive hypercalciuria** is uncommon and is found in patients with primary hyperparathyroidism. Excess parathyroid hormone secretion stimulates intestinal absorption of calcium and mobilization of calcium stores. A brief summary of the metabolic evaluation of children with hypercalciuria is shown in Table 539–2 .

Hyperoxaluria is another potentially important cause of calcium stones. Oxalate increases the solubility product of calcium oxalate crystallization 7 to 10 times more than calcium. Consequently, hyperoxaluria significantly increases the likelihood of calcium oxalate precipitation. Oxalate is found in high concentration in tea, coffee, spinach, and rhubarb. *Primary hyperoxaluria* is a rare autosomal recessive disorder that can be subclassified into glycolic aciduria and L-glyceric aciduria. Most patients with primary hyperoxaluria have glycolic aciduria; oxalic and glycolic acids are increased in the urine of affected individuals. Both defects cause increased endogenous production of oxalate, with hyperoxaluria, urolithiasis, nephrocalcinosis, and renal injury. Death from renal failure occurs by age 20 yr in untreated patients. Oxalosis, defined as extrarenal deposition of calcium oxalate, occurs when renal insufficiency is present with elevated plasma oxalate. Calcium oxalate deposits appear first in blood vessels and bone marrow, and with time they appear throughout the body. *Secondary hyperoxaluria* is more common and can occur in patients with increased intake of oxalate and oxalate precursors such as vitamin C, in those with pyridoxine deficiency, and in children with intestinal malabsorption.

Enteric hyperoxaluria refers to disorders such as inflammatory bowel disease, pancreatic insufficiency, and biliary disease, in which there is gastrointestinal malabsorption of fatty acids, which bind intraluminal calcium and form salts that are excreted in the feces. Normally, calcium forms a complex with oxalate to reduce oxalate absorption, but if calcium is unavailable, there is increased absorption of unbound oxalate.

TABLE 539-2 -- **Metabolic Evaluation of Children with Hypercalciuria**

	Serum Calcium	Restricted Calcium (Urine)	Fasting Calcium (Urine)	Calcium Load (Urine)	Parathyroid Hormone (Serum)
Absorptive	N	N or I	N	I	I
Renal	N	I	I	I	N
Resorptive	I	I	I	I	I

N = Normal; I = increased.

Hypocitruria refers to a low excretion of citrate, which is an inhibitor of calcium stone formation. Citrate acts as an inhibitor of calcium urolithiasis by forming complexes with calcium, increasing the solubility of calcium in the urine, and inhibiting the aggregation of calcium phosphate and calcium oxalate crystals. Disorders such as chronic diarrhea, intestinal malabsorption, and renal tubular acidosis may cause hypocitruria. It may also be idiopathic.

Renal tubular acidosis (RTA) is a syndrome involving a disturbance of acid-base balance within the kidney that can be classified into three types, one of which predisposes to renal calculi that are typically calcium phosphate. In type 1, the distal nephron does not secrete hydrogen ion into the distal tubule. The urine pH is never less than 5.8, and hyperchloremic hypokalemic acidosis results. Patients acquire nephrolithiasis, nephrocalcinosis, muscle weakness, and osteomalacia. Type 1 RTA can be an autosomal dominant disorder, but more often it is acquired and associated with systemic diseases such as Sjögren syndrome, Wilson disease, primary biliary cirrhosis, and lymphocytic thyroiditis, or it results from amphotericin B, lithium, or toluene (an organic solvent associated with glue sniffing).

Five to 8% of individuals with *cystic fibrosis* have urolithiasis. Typically the stones are calcium and often become manifest in adolescence or young adulthood. Microscopic nephrocalcinosis also occurs in younger children with the disease. These patients do not have hypercalciuria, and the propensity for urolithiasis has been speculated to

result from an inability to excrete a sodium chloride load or from intestinal malabsorption.

Other disorders may play a role in causing calcium stones. *Hyperuricosuria* may be related to the epitactic growth of calcium oxalate crystals around a nucleus of uric acid crystals or to the action of uric acid as a counterinhibitor of urinary mucopolysaccharides, which inhibit calcium oxalate crystallization. *Heterozygous cystinuria* is found in some patients with calcium stones. The mechanism is unknown but may be similar to that of uric acid. *Sarcoidosis* causes an increased sensitivity to vitamin D_3 and thus an increased absorption of calcium from the gastrointestinal tract. In *Lesch-Nyhan syndrome*, there is excessive uric acid synthesis. These patients are more likely to form uric acid stones, but some of these stones may be calcified. *Immobility* may cause hypercalciuria by mobilization of calcium stores. High-dose *corticosteroids* may cause hypercalciuria and calcium oxalate precipitation. *Furosemide,* which is administered in the neonatal intensive care unit, also can cause severe hypercalciuria, urolithiasis, and nephrocalcinosis.

In some children, calcium calculi are *idiopathic*. This diagnosis should not be given until a complete metabolic evaluation has been performed.

CYSTINE CALCULI.

Cystinuria accounts for 1% of renal calculi in children. The condition is a rare autosomal recessive disorder of the epithelial cells of the renal tubule that prevents absorption of the four dibasic amino acids (cystine, ornithine, arginine, and lysine) and results in excessive urinary excretion of these products. The only known complication of this familial disease is the formation of calculi, because of the low solubility of cystine. The patients usually have acidic urine, which leads to a higher rate of precipitation. In the homozygous patient, the daily excretion of cystine usually exceeds 500?mg, and stone

formation occurs at an early age. Heterozygotes excrete 100 to 300?mg/day and typically do not have clinical urolithiasis. The sulfur content of cystine gives these stones their faint radiopaque appearance.

STRUVITE CALCULI.

Urinary tract infections caused by urea-splitting organisms (most often *Proteus*, and occasionally *Klebsiella, Escherichia coli, Pseudomonas,* and others) result in urinary alkalinization and excessive production of ammonia, which can lead to the precipitation of magnesium ammonium phosphate (struvite) and calcium phosphate. In the kidney, often the calculi have a staghorn configuration, filling the calyces. The stones act as foreign bodies, causing obstruction, perpetuating infection, and causing gradual renal damage. Patients with struvite stones may also have metabolic abnormalities that predispose to stone formation. These stones are often seen in children with neuropathic bladder dysfunction, particularly those who have undergone an ileal conduit procedure. In children who have undergone urinary tract reconstruction with augmentation cystoplasty or continent diversion, or both, struvite stones may form in the reconstructed bladder.

URIC ACID CALCULI.

Calculi containing uric acid represent less than 5% of all cases of lithiasis in children in the United States but are more common in less developed areas of the world. Hyperuricosuria with or without hyperuricemia is the common underlying factor in most cases. The stones are radiolucent. The diagnosis should be suspected when there is a persistently acid urine and urate crystalluria.

Hyperuricosuria may result from various inborn errors of purine metabolism that lead to overproduction of uric acid, the end product of purine metabolism in humans. Children with the Lesch-Nyhan syndrome and patients with glucose-6-phosphatase deficiency form urate calculi as well. In children with short-bowel syndrome, and particularly those with ileostomies, chronic dehydration and acidosis are sometimes complicated by uric acid lithiasis.

One of the most common causes of uric acid lithiasis is the rapid turnover of purine with some tumors and myeloproliferative diseases. The risk of uric acid lithiasis is especially great when treatment of these diseases causes rapid breakdown of nucleoproteins. Uric acid calculi or “sludge” can fill the entire upper collecting system and cause renal failure and even anuria. Urates are also present within calcium-containing stones. In these cases, more than one predisposing factor for stone formation may exist. A related disorder is *2,8-dihydroxyadeninelithiasis,* which results from a deficiency in adenine phosphoribosyltransferase. The stones are radiolucent and can be differentiated from uric acid calculi by mass spectrometry but not by routine chemical analysis. In contrast to uric acid, which is soluble in alkaline urine, the solubility of 2,8-dihydroxyadenine changes little within physiologic pH ranges.

INDINAVIR CALCULI.

Indinavir sulfate is a protease inhibitor approved for the treatment of human immunodeficiency virus infection. As many as 4% of patients acquire symptomatic nephrolithiasis. Most of the calculi are radiolucent and composed of indinavir-based monohydrate, although calcium oxalate or phosphate, or both, have been present in some. After each dose, 12% of the drug is excreted unchanged in the urine. The urine in these patients often contains crystals of characteristic rectangles and fan-shaped or starburst crystals. Indinavir is soluble at a pH of less than 5.5. Consequently, dissolution therapy by urinary acidification with ammonium chloride or ascorbic acid should be considered.

NEPHROCALCINOSIS.

Nephrocalcinosis refers to calcium deposition within the renal tissue. Often nephrocalcinosis is associated with urolithiasis. The most common causes are furosemide (administered to premature neonates), distal RTA, hyperparathyroidism, medullary sponge kidney, hypophosphatemic rickets, sarcoidosis, cortical necrosis, hyperoxaluria, prolonged immobilization, Cushing syndrome, hyperuricosuria, and

renal candidiasis.

Treatment.

In a child with a renal or ureteral calculus, the decision whether to remove the stone is dependent on the location, size, and composition (if known) and whether obstruction or infection, or both, is present. Small ureteral calculi often pass spontaneously, although the child may experience severe renal colic. The narrow parts of the ureter include the ureteropelvic junction and the midureter, where it crosses the common iliac artery; the narrowest segment is the ureterovesical junction. In some cases, passage of a ureteral stent past the stone endoscopically allows relief of pain and dilates the ureter sufficiently to allow the calculus to pass. In cases such as children with a uric acid calculus or an infant with a furosemide-associated calculus, dissolution therapy may be effective.

If the calculus does not pass or seems unlikely to pass, or if there is associated urinary tract infection, removal is necessary. Lithotripsy of bladder, ureteral, and small renal pelvic calculi using the holmium laser through a flexible or rigid ureteroscope is most effective. Extracorporeal shock wave lithotripsy has been successfully applied to children with renal and ureteral stones at a success rate of more than 75%.

In children with urolithiasis, treatment of the underlying metabolic disorder should be addressed. Because lithiasis results from having too high a concentration of specific substances in the urine, often an effective method of preventing further stones is by maintaining a continuous high urine output by maintaining a high fluid intake. The high fluid intake should be continued at night, and usually it is necessary to get up at least once at night to urinate and drink more water.

In children with hypercalciuria, some reduction in calcium and sodium intake is necessary, but caution is urged in the growing child. Thiazide diuretics also reduce renal calcium excretion. Addition of potassium citrate, an inhibitor of calcium stones, with a dosage of 1–2?mEq/kg/24?hr is beneficial. An excellent source of citrate is lemonade, because 4 ounces of lemon juice contains 84?mEq of citric acid. A daily mixture of 4 ounces of reconstituted lemon juice in 2?L of water and sweetened to taste should significantly increase the urinary citrate level. In difficult cases, neutral orthophosphate should be given also, although it is poorly tolerated.

In patients with uric acid stones, allopurinol is effective. Allopurinol is an inhibitor of xanthine oxidase and is effective in reducing the production of both uric acid and 2,8-dihydroxyadenine and can help control recurrence of both types of stones. In addition, urinary alkalinization with sodium bicarbonate or sodium citrate is beneficial. The urine pH should be at least 6.5 and can be monitored at home by the family.

Maintaining a high urine pH can also prevent recurrence of cystine calculi. Cystine is much more soluble when the urinary pH is greater than 7.5, and alkalinization of urine with sodium bicarbonate or sodium citrate is effective. Another important medication is d-penicillamine, which is a chelating agent that binds to cysteine or homocystine, increasing the solubility of the product. Although poorly tolerated by many patients, it has been reported to be effective in dissolving cystine stones and in preventing recurrences when hydration and urinary alkalinization fail.

N-Acetylcysteine appears to have low toxicity and may be effective in controlling cystinuria, but long-term experience with it is lacking.

Treatment of type 1 RTA involves correction of the metabolic acidosis and replacement of potassium and sodium loss. Sodium or potassium citrate therapy, or both, is necessary. When the metabolic acidosis is corrected, the urinary citrate excretion returns to normal.

Treatment of primary hyperoxaluria involves hepatic transplantation because the defective enzymes are hepatic. Ideally,

---

this procedure should be performed before renal failure occurs. In the most severe cases renal transplantation is also necessary. **REFERENCES**

Part 24 - Gynecologic Problems of Childhood

Joseph S. Sanfilippo

Chapter 540 - History and Physical Examination

Neonatal Infant.

The initial gynecologic assessment of newborn infants should begin with the breast examination. Not uncommonly, as a result of maternal endogenous estrogen production, breast tissue is increased in neonates; nipple discharge may be noted. The abdomen is gently palpated for evidence of organomegaly, and the external genitalia are assessed for any ambiguity. The labia should be grasped gently and separated, allowing inspection of the introitus-hymenal area. Abducting the hips with the labia gently retracted frequently facilitates inspection of the introital area. A normal protuberant hymen with associated thin white mucoid discharge from the vagina is often perceptible. In the first few weeks of life, a small amount of vaginal bleeding may occur, reflecting the decline of circulating levels of maternal estrogens. On completion of the inspection segment of the examination, a rectal examination is performed. A midline structure, indicative of the uterus, is usually palpable, but the adnexa should not be palpable at this time.

Prepubertal Child.

A pediatric or adolescent patient undergoing her first gynecologic examination should be treated with particular care, because the initial encounter may well set the stage for all future gynecologic examinations. If the examination is painful or uncomfortable or if there is significant lack of rapport between the patient and the examiner, the child may suffer lasting psychologic consequences. A gentle, caring attitude by the health care provider will go far in enabling the patient to relax.

The history is obtained primarily from the parent(s), who should be integrally involved in the physical examination of a child in this age group. In addition, patients should have a sense of control over the examination, be involved, and should experience no discomfort. These goals are facilitated by providing an adequate explanation before

the examination.

Much information can be obtained by inspection of the vulvovaginal area. Ideally, a patient is placed in a frog-leg position. If this is not satisfactory, then a knee-chest position with a Valsalva maneuver allows adequate assessment of the introital (lower-third) vaginal area. Magnification often can be accomplished with use of a colposcope or hand-held magnifying glass; appropriate documentation is also important. Visualizing the vestibule permits assessment of any discharge. Aspiration of any fluid in the vagina and lavage should be carried out with aseptic technique: An intravenous tubing (butterfly) is passed into a soft number 12-bladder catheter, all of which is then attached to a 1-mL tuberculin syringe. Wet mounts can be obtained and evaluated as indicated. Cultures should be taken for evaluation of vulvovaginitis. Other instrumentation used for the genital examination includes an otoscope or Cameron-Myers vaginoscope. Gentle traction on the labia upward and outward further exposes the vaginal introitus for assessment. Calcium alginate (Calgi) swabs are also useful, especially for obtaining cultures from the vagina. A number of variations of the normal-appearing hymen occur, and care must be taken to determine if a patient has an imperforate, microperforate, or septate hymen. If an inadequate examination is accomplished in an office-clinic setting, then sedation or examination under anesthesia should be considered.

Adolescent.

Obtaining a history in this age group may initially take place in the presence of the patient's parents. However, an adolescent should be made aware of the concept of confidentiality and be given the opportunity to provide her own history without the parents being present. This can be accomplished in the examination room before the physical examination. Concern for the presence of vaginal discharge, the potential for sexually transmitted disease, pregnancy, or menstrual aberration should be explored. Physicians should win the confidence of the adolescent, provide a relaxed atmosphere for the examination, and communicate one's availability for consultation. Also see Chapters 14 , 17 , and 100 . Indications for the first pelvic examination in adolescents are presented in Box 540–1 .

If an adolescent does not have one of the criteria listed in Box 540–1 , the American College of Obstetricians and Gynecologists recommends that the first “gynecologic encounter” be between the age of 14 and 18 yr. This encounter does not necessitate a pelvic examination but is an opportunity for the physician to provide education for the adolescent.

One suggestion for the adolescent interview is the use of **HEADSS is VG**. This mnemonic is outlined below:

Home—Household, family dynamics and relationships, living arrangements.

Education—School attendance, failed a grade, grades as compared to last year's grades, attitude toward school, most difficult and best subjects, goals: college, career.

Activities—Physical activity, sports, exercise, hobbies, friends, after school, weekends.

Drugs—Cigarettes/smokeless tobacco, alcohol and/or other drugs: use at school or parties; use by friends, self; frequency, and quantity used.

Sexuality—Sexual feelings: Opposite or same sex, sexual intercourse: Age at first intercourse, number of lifetime and current partners, recent change in partners, contraception, sexually transmitted infection, prior pregnancies, abortions.

Suicide/depression—Feelings about self, history of depression or other mental health problems, prior suicidal thoughts, prior suicide attempts, sleep problems.

Box 540-1. Suggested Indications for Pelvic Examination in Adolescents

- Age 18
- Sexually active
- Past or current
    - Menstrual irregularities
    - Severe dysmenorrhea
    - Unexplained abdominal pain
    - Unexplained dysuria
    - Abnormal vaginal discharge

Modified from The adolescent obstetric-gynecologic patient. ACOG Technical Bull 1990;145:3.

Violence—How are conflicts handled in the home (i.e., late for curfew), school, work, guns in the home, weapon carrying, nonconsensual sex, physical contact.

Gangs—Member, friends in gangs, number present in high school, gang markings on skin.

The most important factor with respect to the interview is to establish rapport. During this time the rules of confidentiality should be emphasized with the patient. Sufficient time should be allowed for the office visit. This segment of the interview process (history) should be one-on-one patient and physician.

Pelvic Examination.

The teenage patient, in a manner similar to that for a pediatric patient, should be involved in the pelvic examination. The examination is best performed in the absence of the parents, but a female chaperone should be present and may serve to neutralize any adverse psychosocial aspects of the situation. Communication should occur between the physician and the patient throughout the examination. The examination should be performed in the dorsal lithotomy position with an effort made to maintain eye contact. Appropriate-sized specula should be available, including the small Pedersen's (8?cm in depth). The 4–5-cm speculum is best avoided because it usually results in inadequate visualization; however, the pediatric-sized Huffman speculum is appropriate.

Inspection of the vulva is followed by palpation of the Bartholin's–urethral Skene's glands. The clitoris, which is normally 2–4?mm wide, is then assessed. A clitoris wider than 10?mm, especially in the presence of other signs of virilization, is abnormal. The hymenal configuration should also be evaluated. A patient should be told immediately prior to the insertion of the speculum that she will experience a pressure sensation. Before touching the introitus, it is useful to touch the inner thigh with the speculum. Trauma to the urethra should be avoided, and displacement of the fourchette posteriorly further facilitates proper speculum placement. Discussion with the adolescent about techniques to relax the perineal musculature is often helpful.

Once the speculum portion of the examination is complete, a bimanual examination is undertaken. In a virginal female, a single digit examination with an appropriately lubricated, gloved finger allows proper palpation of the vaginal walls and cervix and bimanual assessment of the uterus and the adnexa. The cul-de-sac is assessed, and a rectovaginal examination performed to complete the bimanual examination.

A number of resources for education of adolescents regarding their first pelvic examination are available. These include:

- North American Society for Pediatric and Adolescent Gynecology. HTTP://www.naspag.org
- The Society for Adolescent Medicine. HTTP://www.adolescent.health.org
- Aware Foundation. HTTP://www.aware foundation.org
- Association of Reproductive Health Professionals. HTTP://www.arhp.org
- GYN101. HTTP://www.gyn101.com

A “tool kit” is available through the American College of Obstetricians and Gynecologists; it includes information on how to establish an office-friendly environment for the adolescent gynecologic evaluation, tools for adolescent assessment, suggestions about how to talk with teens, handouts for adolescents, and a number of resources for health care professionals. (Address: 409 12th Street, SW, PO Box 96920, Washington, DC 20090-6920.)

Chapter 541 - Vulvovaginitis

Vulvovaginitis is the most common childhood or adolescent gynecologic problem. The main clinical manifestations, in order of frequency, include vaginal discharge, erythema, and pruritus. Vulvovaginal irritation results from the lack of labial fat pads and pubic hair for protection of the external genitalia. The labia minora tend to open when a child squats; this, in turn, causes exposure of the sensitive tissues within the hymenal ring. In addition, the close proximity of the anal orifice to the vagina allows transfer of fecal bacteria to the vulvovaginal area. Masturbation may also be a contributing factor.

In the relatively low estrogenic prepubertal environment, the thin atrophic vaginal epithelium is susceptible to bacterial invasion. Recurrent vulvovaginitis usually ceases once a girl reaches puberty, estrogen increases, and the pH of the vagina becomes more acidic. In part, this change results from increased production of acetic and lactic acids, a phenomenon accompanied by an increase in superficial cell proliferation and glycogen as well as by enhancement of normal bacterial flora (Table 541–1).

Vaginal culture, cytology, and vaginoscopy may be indicated for evaluation of pediatric patients with vulvovaginitis. Leukocyte esterase dipsticks are a rapid screening test for vaginitis and cervicitis. The technique has been used to identify trichomonads, *Candida*, and bacterial vaginosis and to evaluate cervical secretions for identification of gonococcal and chlamydial infections.

Physiologic Leukorrhea.

This discharge reflects circulating estrogen levels. Treatment consists of reassurance that this normal process is self-limited.

Pathologic Vaginal Discharge.

In pediatric patients, vaginal discharge is a common presenting complaint. It is often the primary symptom of vulvitis, vaginitis, or vulvovaginitis. Pruritus, frequent urination, dysuria, or enuresis may be associated signs and symptoms. Vulvitis is manifested primarily by dysuria and pruritus and is associated with erythema of the vulva. It commonly has a more protracted course than vaginitis; the latter is characterized by discharge without associated dysuria, pruritus, or erythema. Vulvovaginitis involves a combination of these manifestations. The color, odor, and duration of the discharge should be noted. Although there are a number of causes of vulvovaginitis in pediatric patients, the more common ones include poor perineal hygiene, *Candida* infection, and a foreign body.

Nonspecific Vulvovaginitis.

Patients with poor perineal hygiene often develop a condition known as nonspecific vulvovaginitis. This condition accounts for 70% of all pediatric vulvovaginitis cases. The discharge is characteristically brown or green, has a fetid odor, and is associated with vaginal pH of 4.7–6. In 68% of reported cases, this vaginitis is associated with coliform bacteria

TABLE 541-1 -- **Specific Vulvovaginiti**

Organism	Presentation	Diagnosis	Treatment
Enterobiasis (pinworms)	Perineal pruritus (nocturnal); gastrointestinal symptoms; variable vulvovaginal contamination from feces	Adult worms in stool or eggs on perianal skin	Mebendazole; repeat in 3 wk if necessary
Giardiasis	Asymptomatic fecal contaminant, vaginal discharge, diarrhea, malabsorption syndrome	Protozoal flagellate (cyst or trophozoites) in feces	Metronidazole or quinacrine
Molluscum contagiosum	Vulvar lesions, nodules with umbilicated area; white core of curdlike material	Isolation of poxvirus	Dermal curettage of papule
Phthirus pubis (pediculosis pubis)	Pruritus, excoriation, sky-blue macules; inner thigh or lower abdomen	Nits on hair shafts, lice—skin or clothing	Lindane lotion (Kwell); also see Chapter 658

Sarcoptes scabiei (scabies)	Nocturnal pruritus, pruritic vesicles, pustules in runs	Mites; ova black, dots of feces (microscopic)	1% lindane
Shigella species (shigellosis)	Fever, malaise, fecal contamination, diarrhea; blood and mucus, cramps, pus in stool	Stools; white blood cells and red blood cells, positive for *Shigella*	Trimethoprim and sulfamethoxazole; chloramphenicol, ampicillin, or tetracycline
Staphylococcus and *Streptococcus*	Vaginal discharge to vulvovaginal area; spread from primary lesion	Positive culture results of appropriate organism	Penicillin or cephalosporin
From Sanfilippo J: Adolescent girls with vaginal discharge. Pediatr Ann 1986;15:509.			

secondary to fecal contamination. The next most common bacterial organisms associated with nonspecific vulvovaginitis are hemolytic *Streptococcus* and coagulase-positive *Staphylococcus*. These organisms are often transmitted manually from the nasopharynx. Clothing, chemicals, cosmetics, and soap products or detergents used for bathing or laundry may also cause irritation that leads to nonspecific vulvovaginitis. Tight-fitting clothing, such as jeans, leotards, and tights, as well as rubber pants or plastic-coated paper diapers, have also been implicated. Nonspecific vulvovaginitis occasionally can result in chronic infection, which may cause significant psychologic consequences for a child and her parents alike. Physical examination should emphasize the importance of avoiding “vaginal fixation,” while encouraging proper perineal hygiene.

Successful treatment of nonspecific vulvovaginitis should include instruction in perineal hygiene, switching from tight-fitting underwear, the use of sitz baths with mild soap, and air-drying the vulva. Patients should be instructed in appropriate bowel and bladder habits, emphasizing the need to wipe fecal material away from the vulvovaginal area. Recurrent vulvovaginitis should be treated with systemic antibiotics such as amoxicillin or cephalosporins. Topical estrogen cream or polysporin ointment is often helpful.

Specific Vulvovaginitis.

Gardnerella vaginalis is the most common organism cultured in pediatric or adolescent patients with vulvovaginitis, followed by *Candida*. Other identified organisms include enterococci and anaerobic bacteria such as *Peptococcus*, *Peptostreptococcus*, *Veillonella parvula*, *Eubacterium*, *Propionibacterium*, and *Bacteroides* species. Protozoa, helminths, and viruses should also be considered as etiologic agents. Treatment depends on the offending organism (see Table 541–1).

Vaginal Cysts.

These cysts are uncommon and frequently incidental findings. They represent rests of the wolffian or müllerian ducts or an epithelial inclusion cyst. Management depends on their location and appearance. They are usually observed, but resection is recommended if they become symptomatic.

Gartner Duct Cyst.

These represent a rudimentary portion of wolffian duct. In girls, the duct usually regresses completely. However, it may have remnants along the anterolateral walls of the vagina. The cysts have been associated with dyspareunia in sexually active adolescents. This symptomatology warrants surgical resection.

Clitoral Synechiae.

These are often associated with pruritus involving the clitoral area and may result from rubbing of the anterior genital area during ambulation. Erythema is variable. The examination should attempt to gently slide the clitoral skin fold back from the glans clitoris. The clitoral hood appears to be agglutinated to the glans clitoris and may be painful when evaluated. Treatment consists of applying estrogen cream to the peri-clitoral area daily over a 1–2-wk period. This usually suffices; however, surgical intervention may be warranted.

Labial Adhesions.

In this disorder, the labia minora have a central line of adherence from an area immediately inferior to the clitoris to the fourchette (Fig. 541–1 (Figure Not Available)). Labial adhesions are commonly seen in patients younger than 6 yr of age, and the condition is often asymptomatic. The lesions usually are associated with local inflammation and the hypoestrogenic state of preadolescents. Pooling of urine in the vagina and recurrent vulvovaginitis provide a continuous nidus for recurrent urinary tract infections. These urinary symptoms occur in 20–40% of patients and should be treated.

Topical estrogen cream applied each evening for 1 wk is the treatment of choice and is effective in over 90% of reported cases. Cleansing followed by periodic application of a bland ointment such as petrolatum or zinc oxide should continue for 1–2 mo after the adhesions separate to prevent recurrence.

Figure 541-1 (Figure Not Available) Labial adhesions.

Mechanical separation of the adhesions is advisable only if the adhesions appear to separate easily and if it does not cause significant trauma. Once the adhesions are

separated, the patient should be re-examined for any predisposing cause, such as the presence of a vaginal septum.

Candidiasis.

Candida infection is often associated with a diaper rash. *Candida* vulvovaginitis, though rare in children, must be considered, especially for girls with chronic mucocutaneous candidiasis. The presence of *Candida*-infected tissue may be indicative of significant immunosuppression. Underlying factors such as diabetes mellitus should be considered. Treatment with an imidazole cream (e.g., clotrimazole) is frequently effective, except in cases of chronic mucocutaneous candidiasis. Also see Chapter 215 .

Molluscum Contagiosum.

This common infection of the skin is caused by molluscum contagiosum virus, or poxvirus. Molluscum contagiosum presents as an umbilicated, dome-shaped papule. The central umbilication is usually associated with a pulpy core. Vulvar lesions appear to result from autoinoculation or from close contact (sexual or nonsexual) with an infected individual. The incubation period is 2–7 wk. Diagnosis is confirmed by light microscopic visualization of viral inclusions (molluscum bodies) in the central core. Treatment requires elimination of the lesions, usually by gentle curettage; other methods of therapy include cryosurgery or electrocautery.

Intertrigo.

Intertrigo can occur in the genitocrural areas in association with friction, obesity, and moisture in the area. Miliaria and secondary infection can also occur in association with intertrigo. The affected areas are red and macerated. Careful hygiene, combined with bland emollients and sometimes a mild corticosteroid, is an effective treatment.

Impetigo.

This entity is commonly identified during the first several weeks of life. It is usually caused by *Staphylococcus aureus*, often phage group II, type 71, which may be acquired from the mother, other relatives, or staff. Impetigo tends to affect the vulva and periumbilical areas, causing lesions or blisters that later become crusted. Extensive spread and complications may ensue if treatment with antibiotics is not promptly instituted. Also see Chapter 166 .

Malassezia Furfur.

This condition is caused by *Pityrosporum orbiculare* and is manifested by scaly macules on the trunk in postpubertal patients, but lesions have been reported on the face and genital area. The diagnosis is established by visualization of hyphae and spores on wet preparation with 10% potassium hydroxide. Treatment requires application of topical imidazoles (e.g., clotrimazole). Also see Chapter 217 .

Herpes Simplex Virus.

Herpes simplex virus (HSV) types 1 and 2 involve the vulvar area. The types are not exclusively site specific, but type 2 is commonly responsible for genital lesions and type 1, in general, for facial-oral lesions. The infection is characterized by papules that become vesicles, with the virus affecting the dorsal root ganglia. Differential diagnoses include any eroded or blistering lesions as well as herpes zoster. A definitive diagnosis is established by culturing the virus or visualizing it via electron microscopy. Treatment with topical acyclovir reduces viral shedding and accelerates healing. See Chapter 231 .

Human Papillomavirus (HPV).

HPV is associated with a number of serotypes, including 6, 11, 16, and 18, which usually are noted in the anogenital region. Types 16 and 18 are particularly associated with malignant and premalignant lesions of the vulva. Differential diagnoses include molluscum contagiosum, condyloma acuminatum, and vulvar intraepithelial neoplasia. The possibility of child sexual abuse must be strongly considered when these lesions are identified. Treatment is based upon presenting signs and symptoms. See Chapter 243 .

Lichen Sclerosus

CLINICAL MANIFESTATIONS.

This is a chronic atrophic skin disease characterized by small, pink to ivory, flat-topped papules that are several millimeters in diameter. The papules appear to coalesce into plaques that become wrinkled and atrophic. The anogenital lesions frequently resemble an hourglass or a figure 8 (Fig. 541–2 (Figure Not Available)). Vesicles and bullae may spread over the vulva with associated hemorrhage. Lichen sclerosus commonly presents in the prepubertal patient; 10–15% of all cases of lichen sclerosus occur in children. Also see Chapter 645 .

The onset of lichen sclerosus in most children usually occurs before 7 yr of age. The youngest reported patient was an infant several weeks old. The onset of menarche often results in spontaneous improvement of the lesions, but the process usually continues. Patients are often intermittently symptomatic, and there is no relationship between menarche and symptomatic improvement or resolution of the disease. Atrophy of the labia minora and clitoral phimosis, as well as contracture of the introitus, may occur.

ETIOLOGY.

The cause of lichen sclerosus is unknown, but it is believed to be related to an autoimmune disorder. There is an association with certain HLA types. Family clusters have now been documented. There may be a relationship between lichen sclerosus and morphea (localized scleroderma or the spirochete *Borrelia*). Decreased 5-alpha reductase activity has also been proposed as a possible cause for lichen sclerosus. Positive immunofluorescence for fibrin, serum complement (C3),

or immunoglobulin M (IgM) in the involved area has been demonstrated in 75% of patients.

TREATMENT.

This is symptomatic; emollients and topical corticosteroids usually provide relief. Corticosteroids are the treatment of choice for lichen sclerosus in adults and have been efficacious in children as well. Initially, 1–2% hydrocortisone cream is used. If there is failure to respond, a short course of betamethasone dipropionate 0.05% or clotrimazole is recommended. Minimal side effects are associated with this treatment. After the initial response, a milder topical corticosteroid may be used to prevent recurrence. Topical estrogens and androgens also have been advocated, but these agents may produce a vaginal

Figure 541-2 (Figure Not Available) Lichen sclerosus.

---

discharge as well as other secondary problems, such as breast development and clitoral enlargement. Secondary infections should be treated with antibiotics. Some affected individuals demonstrate Koebner phenomenon; these individuals should avoid tight-fitting clothing and genital trauma. Laser vaporization has also been advocated.

Lichen Planus.

Vulvar lichen planus is often associated with oral mucosal and subcutaneous lesions. The vulvar lesions are characterized by angular violaceous, flat-topped papules and may simulate leukoplakia. In addition, the oral lesions consist of minute white papules that form a lacy pattern and usually are located on the buccal mucosa. The lesions are intensely pruritic and may become excoriated and macerated; erosions and ulcerations may occur in severe cases. Diagnosis requires biopsy. Exacerbation or recurrence of the lesions is common.

Treatment consists of topical intralesional corticosteroids and antihistamines to control the pruritus. Squamous cell carcinoma may occur with long-standing, hypertrophic, vulvar lichen planus; therefore, long-term follow-up and histologic examination of any changes or otherwise suspicious areas is advisable.

Lichen Simplex Chronicus (Neurodermatitis).

This is a chronic, lichenified plaque that causes pruritus. It results from persistent rubbing and scratching of the vulvar skin; excoriations and fissuring occur. The labia have the appearance of white, hypertrophic, edematous lesions. The changes can occur on the mons pubis as well as the labia majora. Scratching and inflammation may result, causing a vicious cycle. The condition is rare in children. Treatment with antihistamines and topical or intralesional corticosteroids is recommended. Triamcinolone (5–10?mg/mL) has been utilized for intralesional injection.

Seborrheic Dermatitis.

This presents as erythematous, oily, circumscribed patches that can be found on the face, scalp and chest as well as on the intertriginous areas of the body. There may also be fissures and associated secondary infection around the vulva; secondary bacterial or candidal infection is quite common, causing pain, pruritus, dysuria, and vaginal bleeding. Acute episodes are best *treated* with sitz bath or topical aluminum acetate solution (Burow solution). Exacerbating factors, such as tight clothing or rubber pants, should be eliminated. Systemic antibiotics with appropriate topical antifungal medication should be administered for secondary infection.

Atopic Dermatitis.

This affects 3% of all children (also see Chapter 135). Patients present with hay fever or asthma or both, and generally a family history is noted. The vulvar lesion is characterized as a chronic condition accompanied by intense pruritus, erythema, papules, and vesicles, with oozing and crusting of the involved areas. Associated circumscribed, lichenified scaly patches may be seen on the vulvar area. Pruritus often causes scratching, which results in excoriation of the lesions. Secondary bacterial or candidal infection is common.

Antihistamines are necessary for control of pruritus. Sitz baths with mild soap and lubricants are helpful. Topical corticosteroids such as 1% hydrocortisone are also effective. Secondary bacterial or candidal infections require specific treatment.

Dermatitis.

In either allergic or irritant contact dermatitis, the vulva may be affected by edematous, erythematous, oozing lesions that are sometimes accompanied by vesicles or pustules. Chronic contact dermatitis is often associated with thickened and lichenified lesions. The clue to correct diagnosis of this condition is the limitation of the dermatitis to the area of contact with the etiologic agent. There may also be a secondary candidal or bacterial infection. Some common etiologic agents are soaps, powders, bubble baths, feminine hygiene sprays, topical medications, toilet paper, rubber, and certain types of clothing.

Treatment should include avoidance of the offending agents and sitz baths, or compresses with topical aluminum acetate solution (Burow solution) during acute episodes. Mild topical corticosteroids such as 0.5–1% hydrocortisone cream applied several times daily may further aid healing and alleviate vulvar irritation. Recurrence can be prevented by removal of the offending etiologic agent.

Folliculitis.

This can occur either spontaneously or secondary to shaving or other depilatory methods such as waxing. It results in a papulopustular eruption secondary to inflammation of the hair follicle. It may occur in any hair-bearing skin. On physical examination pustules are identified ranging in size from 2–10?mm. The pustules may be pierced in the center by a visible hair. The pustules become replaced by red

papules. *Staphylococcus aureus* is the most common agent; however, *Pseudomonas aeruginosa* can also occur. The latter is associated with "hot tub folliculitis." Treatment includes sitz baths and cleansing with povidone-iodine solution once or twice a day. When *Staphylococcus* infections do not respond, treatment is with doxycycline, cephalosporins, or erythromycin.

Vulvar Psoriasis.

This is frequently associated with lesions of other parts of the body and is characterized by violaceous papules or plaques with a thick, adherent, silvery scale (Fig. 541–3 (Figure Not Available)). The intertriginous areas may show "inverse" psoriasis, a variation that does not occur on the extremities. Vulvar lesions are poorly demarcated and may present as scaly patches, most commonly on the mons pubis. The vulvar lesions are often resistant to therapy. A corticosteroid cream (e.g., 1% hydrocortisone) should be used in conjunction with control of secondary infection and pruritus.

Enterobiasis.

Pinworms (*Enterobius vermicularis*) are helminths that may carry colonic bacteria to the perineum, causing recurrent vulvovaginitis (also see Chapter 271). Female pinworms emerge from the anus to deposit eggs. Vulvovaginitis develops in about 20% of girls infected with *E. vermicularis*. The plastic tape test should be used to search for the organism if it is suspected or in cases of undiagnosed recurrent vulvovaginitis. Victims typically have pruritus and nocturnal episodes of scratching. Treatment consists of pyrantel pamoate (see Table 541–1).

Figure 541-3 (Figure Not Available) Vulvar psoriasis.

Shigellosis.

Shigella flexneri and *S. sonnei* cause various gastrointestinal symptoms in association with vaginitis. Forty-seven per cent of patients present with a bloody vaginal discharge and 2% with diarrhea. Systemic antibiotics are the treatment of choice. Bowel colonization with *Shigella* can result in subclinical gastrointestinal symptoms in 10% of household members. See Chapter 182 .

Vitiligo.

This presents as sharply demarcated pink to ivory patches that tend to spread and coalesce (Fig. 541–4 (Figure Not Available)). The skin on the patch is smooth and shows no palpable changes. It may be differentiated from lichen sclerosus because the hyperpigmented patches are asymptomatic. No treatment is necessary unless cosmetic problems result.

Aphthous Ulcers.

Aphthous ulcers of the genital region as well as oral mucosa range in size from 1–10?mm and have a grayish-yellow base. These ulcers may recur and last at least 7–10 days. The etiology remains unclear. Vulva lesions can be treated with topical corticosteroids and if necessary topical anesthetics.

Drug Reactions Associated with Vulvar Lesions.

Erythema multiforme can present with genital ulcers complementing lesions on the palms, soles, and other parts of the body. The lesions usually persist for approximately 1 wk. They may represent an allergic reaction to a medication or a preceding flare-up of herpes simplex.

Stevens-Johnson Syndrome.

This is a variant of erythema multiforme with more severe mucosal membrane involvement. Medications that cause Stevens-Johnson syndrome include nonsteroidal antiinflammatory agents, sulfonamides, and some anticonvulsive drugs. *Mycoplasma pneumoniae* can also cause this syndrome. In general, the prodromal period is 1–14 days and is characterized by fever, headaches, sore throat, and malaise. There may also be vomiting and diarrhea. The oral mucosa and the eyes can be affected simultaneously. Also see Chapters 138 and 139 .

Toxic Epidermal Necrolysis.

These lesions are secondary to a number of medications; 20–30% of patients die. The skin appears to be scalded, vulvar erosion and ulceration can be extensive. Resulting vulvar synechiae and atrophy can produce dyspareunia. See Chapter 647 .

Figure 541-4 (Figure Not Available) Vitiligo.

Labial Hypertrophy.

Hypertrophy of the labia minora is uncommon. It may occur either unilaterally or bilaterally. Occasionally, it is symptomatic; the patient complains of irritation or discomfort with walking, riding, biking, or intercourse. In the asymptomatic patient, treatment includes reassurance. However, in the symptomatic patient the excessive tissue can be excised and the skin re-approximated with interrupted sutures or a subcuticular closure. The patient may require a Foley catheter immediately postoperatively.

Crohn Disease.

This is a chronic noncaseating granulomatous disease involving the gastrointestinal tract (see Chapter 317.2). However, gynecologic problems occur in up to 24% of women with Crohn disease. These manifestations include erythema, edema, and

subsequent ulcer formation. Cutaneous ulcers of the vulva are slit-like, deep, and multiple. Secondary infection may occur. The diagnosis must be distinguished from other defects such as sarcoidosis, condyloma acuminata, condyloma lata, and hidradenitis suppurativa. Biopsy confirms the diagnosis. Treatment of the gastrointestinal problem with steroids and antibiotics is the primary objective of management. Vulvar lesions are treated with local application of steroids and systemic antibiotics for secondary infections.

Behçet Disease.

This is a rare chronic multisystem disease associated with occlusive vasculitis (see Chapter 151). It is a multiorgan system problem characterized by recurrent oral and genital aphthous ulcers and uveitis, cutaneous vasculitis, synovitis, and meningoencephalitis. Genital ulcers occur in 58–78% of patients. They are painful, red macular lesions. Symptomatic treatment includes topical anesthetics such as lidocaine jelly. Intralesional steroids may be necessary for symptomatic ulcers. In severe forms of the disease treatment has included colchicine or methotrexate.

Chapter 542 - Bleeding

The entities responsible for isolated vaginal bleeding in the pediatric patient include exposure to exogenous sex steroids; foreign body; hemorrhagic cystitis; hypothyroidism; precocious puberty; an ovarian cyst; trauma, which may or may not be associated with sexual abuse; urethral prolapse; vulvovaginitis; and neoplasms. See Chapter 107 for discussion of menstrual problems.

Foreign Body.

A foreign body is commonly responsible for vaginal bleeding in pediatric patients. A foul-smelling discharge associated with vaginal bleeding suggests this possibility. Wadded toilet paper is the most common foreign body identified in the vagina. A plain roentgenogram or ultrasonography of the pelvis is often helpful. A vaginal foreign body was found in 18% of preadolescent girls with vaginal bleeding with or without discharge and in 50% of those with bleeding and no discharge.

Urethral Prolapse.

Vulvar bleeding can be associated with urethral prolapse. This uncommon disorder is characterized by the urethral mucosa protruding through the meatus and forming a sensitive vulvar mass that bleeds easily. The “mass” is separate from the vagina. Patients may have difficulty with urination, depending on the size of the mass and whether or not it occludes the urethral meatus. The entity responds to topical application of estrogens because the distal urethra is estrogen sensitive. Urethral prolapse is often misdiagnosed when there is urogenital bleeding.

Genital Trauma.

Although most injuries to this area are accidental, the possibility of physical or sexual abuse must be considered (see Chapter 35). Blunt injury may cause blood vessels beneath the perineal skin to rupture. Blood accumulating under the skin forms a hematoma, which may present as a round, tense, tender mass. Contusion of the vulva usually does not require treatment. A small vulvar hematoma often can be controlled by pressure with an ice pack. Analgesics may be required.

Penetrating injuries to the vaginal area warrant further careful evaluation, including serious considerations of the possibility of sexual abuse. A detailed examination is necessary, especially in the presence of active bleeding. The potential for bowel or bladder trauma must also be considered.

Genital Tumors.

Benign and malignant tumors of the vulva should be considered when vaginal bleeding occurs in pediatric patients. A broad spectrum of entities, ranging from capillary hemangiomas through malignancies such as rhabdomyosarcoma, requires appropriate tissue diagnosis and treatment. The most common tumors include endodermal carcinoma, which occurs most often in young children; mesonephric carcinoma, which arises in a remnant of a mesonephric duct and occurs more often in girls 3 yr of age or older; and clear cell adenocarcinoma, which is often associated with a history of antenatal exposure to diethylstilbestrol (see Chapters 495 and 545).

Capillary Venous Malformation of the Labia Majora.

Capillary venous malformation has been reported as a cause of vaginal bleeding in pediatric patients with expansion in vaginal volume on response to hormonal changes at puberty. The differential diagnosis includes hemangioma and other vascular malformation(s). Diagnosis is based on an evaluation that includes ultrasonography, magnetic resonance imaging, and abdominal arteriography. The malformation can be locally excised.

Chapter 543 - Breast Disorders

The mammary glands are derived from the epidermal layer. Beginning at approximately 6 wk of gestation, epidermal cells migrate to the mesenchyme and form the mammary ridges. Breast buds, lactiferous ducts, and fully developed mammary glands eventually form. Breast development normally occurs in girls between the ages of 8½ and 13 yr. The rate of breast growth varies, and development is often asymmetric. Complete development may not occur until a woman is in her early 20s.

Breast Self-Examination.

Early diagnosis is central to improving health care for breast abnormalities, including carcinoma. Instruction in breast self-examination should be given to adolescents (Box 543–1).

Congenital Anomalies.

Complete absence of breast, *amastia*, is rare; it is usually unilateral and often associated with other abnormalities, such as Poland syndrome (aplasia of the pectoralis muscles, rib deformities, webbed fingers, and radial nerve aplasia). Amastia can be iatrogenic, as a result of inadvertent excision of a breast bud. *Athelia* is defined as absence of one or both nipples. This condition is also rare and may not be associated with absent breast tissue. Both abnormalities require surgical correction.

Supernumerary breasts (polymastia) and *supernumerary nipples* (polythelia) are relatively common (Fig. 543–1); they occur

Box 543-1. How to Do Breast Self-Examination

1. Lie down. Flatten your right breast by placing a pillow under your right shoulder. If your breasts are large, use your right hand to hold your right breast while you do the exam with your left hand.
2. Use the sensitive pads of the middle three fingers on your left hand. Feel for lumps using a rubbing motion.
3. Press firmly enough to feel different breast tissues.
4. Completely feel all of the breast and chest area to cover breast tissue that extends toward the shoulder. Allow enough time for a complete exam. Women with small breasts need at least 2 minutes to examine each breast. Larger breasts take longer.
5. Use the same pattern to feel every part of the breast tissue. Choose the method easiest for you. The three patterns preferred by women and their doctors are the circular, clock, or oval pattern; the vertical strip; and the wedge.
6. After you have completely examined your right breast, then examine your left breast using the same method. Compare what you have felt in one breast with the other.
7. You may also want to examine your breasts while bathing, when your skin is wet and lumps may be easier to feel.
8. You can check your breasts in a mirror; look for any change in size or contour, dimpling of the skin, or spontaneous nipple discharge.

Reproduced with permission of the American Cancer Society.

Figure 543-1 Polythelia.

along the milk lines and are usually asymptomatic. There is an association between polythelia and anomalies of the urinary and cardiovascular systems. In general, surgical excision of the accessory breasts or nipples is not necessary. However, if the aberrant breasts or nipples become symptomatic, excision may be indicated.

Hypoplasia of the breasts varies in degree from a nearly total absence of breast tissue to well-formed breasts that are considered by the patient to be too small. There are three general causes for poor or absent breast development: (1) The onset of breast development may be delayed, and the breasts develop slowly but are normal in all other respects; (2) a patient's family history may include late breast development; (3) ovarian function may have failed or been suppressed (see Chapter 580). Treatment depends on the underlying cause.

Breast atrophy is seen occasionally in adolescents and is almost uniformly secondary to dietary changes such as occur with anorexia nervosa. Correction of the underlying problem results in re-establishment of breast tissue.

Neonatal Breast Abnormalities.

Bilateral breast hypertrophy may occur as a result of elevated circulating maternal endogenous steroid hormones in late gestation. It may be associated with discharge from the nipples known as “witch's milk.” Repeated manipulation of the breast can exacerbate the condition. On occasion, the hypertrophy is associated with mastitis caused by a staphylococcal infection; antibiotics should be administered.

Mastodynia.

Painful breast engorgement (mastodynia) usually is associated with ovulatory cycles; this is uncommon in adolescents until approximately 18 mo after menarche, the time that may be necessary to establish ovulatory cycles. There is frequently a cyclic pattern of the breast discomfort. Analgesics such as nonsteroidal anti-inflammatory drugs, including ibuprofen, as well as the use of a good support bra, are often helpful in alleviating discomfort.

Breast Masses.

A retrospective review of breast disease in adolescent females revealed that about 54% have fibroadenomas and 13% have virginal hypertrophy. Fibrocystic or proliferative breast disease occurs in about 24%. Primary rhabdomyosarcoma, metastatic rhabdomyosarcoma, metastatic neuroblastoma, and non-Hodgkin lymphoma occur in 2–3% of all breast masses in this age group. Other diagnoses include polythelia, accessory breast tissue, mastitis, hemangioma, fat necrosis, and intramammary lymph nodes. Breast masses during adolescence may stem from

several causes:

- Fibroadenoma
- Fibrocystic disease
- Breast cyst
- Abscess/mastitis
- Intraductal papilloma
- Fat necrosis/lipoma
- Cystosarcoma phyllodes
- Adenomatous hyperplasia
- Rare lesions (hemangiomas, lymphangiomas, lymphoma)
- Normal breast tissue
- Cancer

A thorough history and physical examination are mandatory for any pediatric or adolescent patient who has a breast mass. The clinical problem should be reviewed with a radiologist before initiating any radiologic assessment. Needle aspiration and biopsy are often essential for evaluation of palpable breast abnormalities. Large breast tumors also occur in adolescents. Although malignancy is often suspected because of rapid growth of the mass and skin ulceration, the incidence is very low. Breast tumors can have varied presentations. Giant fibroadenomas in adolescence may be treated by simple enucleation.

Malignant Tumors.

Although rare, *breast cancer* does occur in adolescents. Early menarche in association with anovulatory cycles is a risk factor. The estrogen-to-androgen ratio appears to be critical, with androgens having a protective effect.

Cystosarcoma phylloides, an uncommon breast tumor in adults, may occur in adolescents. It is characterized by asymmetric breast enlargement in association with a firm, mobile, circumscribed mass. The tumor often increases rapidly in size and can become quite large. Fixation of the tumor to the skin or chest wall is rare. The majority of these tumors are benign, but malignant cystosarcoma phylloides with metastases has been reported. Excision is the preferred initial therapy in adolescent patients, regardless of the histologic classification of the lesion. Malignant cystosarcoma is more likely to recur than is a benign lesion. Fatal metastatic cystosarcoma phylloides in an adolescent has occurred.

Breast tumors also may be the first manifestation of relapse (extramedullary) in *acute lymphoblastic leukemia*. Reports in the literature include a case of radiation-induced sarcoma of the breast in a female adolescent and a case of liposarcoma in a 17-yr-old black female who previously had a total mastectomy.

Macromastia (Virginal Hypertrophy).

The cause of massive breast enlargement during puberty and early adolescence is unknown, but the condition probably represents an end-organ increased sensitivity to circulating estrogens. It is bilateral, often occurs over a brief period, and most commonly affects girls 13–17 yr old. Physical and psychologic problems may occur in adolescents with macromastia. Posture problems and discomfort often result.

Reduction mammoplasty is the treatment of choice but should be delayed until late adolescence to allow for complete breast development. Surgical intervention often necessitates relocation of the nipple, which may result in decreased sensation

and altered lactation. In addition, strong emotional support should be provided.

Tuberous Breasts.

This deformity results in breasts that are reminiscent of a tuberous root plant. It may be the result of an exogenous steroid use, especially with induction of pubertal development. Surgical intervention is required for correction.

Mastitis and Abscess.

Mastitis and breast abscess may require antibiotic therapy as well as incision and drainage. See Chapter 106 .

Trauma and Inflammation.

Breast trauma in adolescent females has become more common because of the increased number of young women participating in contact sports. The trauma usually takes the form of contusion or hematoma and often resolves with either late cystic changes in the breast or fibrosis with retraction of skin or the nipple over the injured area. These late changes may mimic those associated with malignancy; biopsy may be the only means of differentiating the two.

Mammary Dysplasia.

This common lesion is characterized by changes associated with the menstrual cycle. Hormonal imbalance may cause exaggerated responses in the breast tissue, especially in the upper and outer quadrants during the premenstrual phase of the cycle. The extent of treatment depends on the degree of symptoms; ibuprofen is often helpful. In addition, methylxanthines and caffeine (e.g., coffee, tea, carbonated drinks) should be eliminated from the diet.

Nipple Discharge.

This must be carefully evaluated and a distinction made between the presence of galactorrhea (spontaneous flow of milk), bloody, and other discharge (Table 543–1). Evaluation of galactorrhea in children is the same as for adults. Serum prolactin levels are obtained to rule out the presence of a pituitary prolactinoma (see Chapter 554.2). If a pituitary tumor or adenoma is suspected on the basis of markedly elevated serum hemianopsia, appropriate radiologic (computed tomography, magnetic resonance imaging) assessment is necessary. Another cause of galactorrhea is hypothyroidism in association with elevated levels of thyroid-releasing hormone, which also stimulates prolactin release. Medications may also cause

galactorrhea (Table 543–2). Treatment of galactorrhea (non-thyroid related) consists primarily of dopamine agonists such as bromocriptine or cabergoline (Dostinex). Surgical intervention, usually transsphenoidal hypophysectomy, is rarely required. Galactorrhea secondary to chest wall surgery in an adolescent has also been reported. The galactorrhea occurred for 2 mo and was associated with transient amenorrhea.

Bloody nipple discharge can be indicative of duct ectasia. Cytologic assessment and surgical consultation are indicated. Nipple discharge in association with Montgomery tubercles also has been reported. These secretions can be episodic and vary in color from clear to brown, but they are usually not milky. This discharge evolves over a period of 3–5 wk, may be associated

TABLE 543-1 -- Differential Diagnosis of Nipple Discharge

Type	**Differential Diagnosis (in Order of Frequency)**
Milky	Galactorrhea
Multicolored/sticky	Duct ectasia
Purulent	Mastitis
Watery	Papilloma
	Cancer
Serous/serosanguineous	Intraductal papilloma
	Fibrocystic changes
	Cancer
	Duct ectasia

with breast lumps, and is a benign, self-limited problem. Intraductal breast papillomas have occurred in adolescents.

Breast Asymmetry.

Beginning in the neonate there may be unilateral breast development. In adolescents, it is not uncommon for approximately 25% of patients to have an element of breast asymmetry that persists after the age of 18. Asymmetry is common especially between Tanner stage 2 and 4 (see Fig. 14–2).

Chapter 544 - Hirsutism and Polycystic Ovarian Syndrome

Hirsutism (excessive hair growth) must be distinguished from virilization. The latter involves increased body hair, acne, deepening of the voice, change in body habitus due to increased muscle mass, and clitoromegaly (see Chapter 570). Premature pubarche is defined as the appearance of genital hair or axillary hair or both before age 8 yr (Chapter 556). Adrenarche, the output of increased androgen from the adrenal glands, usually occurs between ages 12 and 18 yr and is discussed in Chapter 14 .

Polycystic ovarian syndrome (PCOS) is believed to have its origin at puberty. Teenagers usually present with menstrual disturbances or hirsutism (Box 544–1). Ultrasonographic

assessment often identifies multicystic ovaries, a characteristic “pearl necklace.” The prevalence of polycystic ovaries increases throughout puberty and may reach as high as 26% by 15 yr of age.

PCOS (polycystic ovaries, chronic anovulation, and Stein-Leventhal syndrome) is the most commonly diagnosed ovarian

TABLE 544-1 -- **Treatment of Hirsutism: Idiopathic and Polycystic Ovary Syndrome**

Medication	Dose*	Comments
Oral contraceptives (estrogen dominant)	35?µg	Decrease in plasma testosterone, androstenedione, and DHEA-S
Spironolactone	100?mg bid	Decreased androgen production and androgen receptor competition
Medroxyprogesterone acetate depot (Depo-Provera)	150–250?mg q 2–4 wk	Decreased testosterone production and 17-ketosteroid levels
Cyproterone acetate	Diane, 2?mg Androcur, 100?mg	Decreased plasma testosterone, androstenedione, SHBG, induces “insulinemia”
Dexamethasone	0.25–0.5?mg	Dose adequate if plasma-free testosterone <15 pg/mL
Cimetidine	200–300?mg tid–qid	Decreased serum testosterone, increased serum estradiol
GnRH agonist (Flutamide)	250?mg tid	5a-reductase inhibitor; decreased testosterone and androstenedione

DHEA-S = dehydroepiandrosterone sulfate; SHBG = sex hormone–binding globulin.

From Bailey-Pridham DD, Sanfilippo JS: Hirsutism in the adolescent female.Pediatr Clin North Am 1989;36:581, with permission.

**Dosages given are for a 70-kg female. Daily dosages are indicated unless otherwise specified*

cause of hirsutism, and controversy exists about whether the basic defect is central (hypothalamic or pituitary regulation of gonadotropins) or ovarian (defect in a peptide hormone, perhaps inhibin, with resultant abnormal feedback to the pituitary gland). The usual hormonal pattern of PCOS begins with altered luteinizing hormone release (a ratio of luteinizing hormone [LH] to follicle-stimulating hormone of 2:1 or 3:1, shortened pulse frequency, and slightly increased pulse amplitude of LH). Adolescents with hyperandrogenism display an exaggerated LH pulsatility similar to that found in adults with PCOS syndrome.

PCOS is associated with peripheral insulin resistance in addition to excessive levels of LH, resulting in increased ovarian androgen production. Hyperinsulinemia is associated with increased bioavailable insulin-like growth factor-1 (IGF-1) and depressed production of IGF-1 carrier protein (IGFBP-1). Activation of IGF-1 receptor may also be involved in increased ovarian androgen production. Peripheral conversion of ovarian androstenedione to testosterone contributes to the commonly identified increase in total serum testosterone levels that are an integral part of the PCOS hormonal pattern. In addition to their hyperinsulinemic state, these patients have long-term cardiovascular risks for hypertension and coronary artery disease. This patient population often also has increases in total triglyceride levels.

The insulin resistance is an integral part of the *HAIR-AN syndrome*, which consists of hyperandrogenism, hirsutism, insulin resistance, and acanthosis nigricans. Insulin receptor mutation as well as circulating antibodies to the insulin receptor and postreceptor defects occur in this syndrome. Defects in glucose transport as well as high levels of insulin stimulate the activity of cytochrome P450c 17a, an enzyme actively involved in the production of androgens by the ovary. With PCOS there is also dysregulation of the cytochrome P450c 17a enzyme system.

Hirsutism in adolescents can also be due to a heterozygous form of *21-hydroxylase deficiency* (see Chapter 570). This has been called adult-onset congenital adrenal hyperplasia (AOCAH). Various other forms of congenital adrenal hyperplasia and congenital anomalies are also associated with hirsutism. Clinically, it may be difficult to distinguish between PCOS and AOCAH.

Ovarian hyperthecosis, which can be familial, is a variant of PCOS. Hyperthecosis is defined as isolated islands of luteinized cells within the ovary, contributing to increased androgen production. Ovarian androgen production and its peripheral effects are similar to those associated with PCOS.

Medications, radiation, and chronic irritation (e.g., the placement of a cast) can also

initiate localized, nonendocrinologic hair growth.

Treatment of Hirsute Patients.

Treatment alternatives for idiopathic hirsutism and PCOS are outlined in Table 544–1 . Hirsutism secondary to hyperprolactinemia is best treated with bromocriptine. In patients with multicystic (polycystic) ovaries and primary hypothyroidism, the polycystic ovaries resolve rapidly with adequate doses of thyroid replacement therapy. If an exogenous cause such as a medication is producing hirsutism, the exogenous agent should be eliminated. Even when the increased tissue androgen effect is reversed by appropriate treatment, hair follicles converted to terminal hair may still produce that type of hair. Electrolysis may provide an improved cosmetic appearance, with the assurance that if the underlying abnormality is controlled, no new hair growth should ensue. Cushing syndrome or disease, androgen-producing tumors, and congenital adrenal hyperplasia are discussed in Chapters 570 and 571 .

Metformin, an insulin-sensitizing agent, has been recommended for hyperinsulinemic PCOS patients. The objective is to reduce circulating insulin levels, which is associated with decreases in serum LH and testosterone with PCOS. This result occurs within 4 to 8 wk. It is imperative that treated patients have pre-therapy, as well as periodic, evaluation of liver function.

Chapter 545 - Neoplasms

The most common gynecologic neoplasm found in children is of ovarian origin and usually presents as an abdominal mass. Ovarian neoplasms constitute 1% of all childhood malignancies, and 8% of all malignant and abdominal tumors in children are of ovarian origin. Furthermore, 10–30% of the ovarian neoplasms operated on during childhood or adolescence are malignant. Paraovarian tumors are next in frequency, followed by uterine neoplasms. The vagina or vulva may also be the site of a benign or malignant lesion in children. Cervical dysplasia may occur in adolescents. Breast masses are discussed in Chapter 543 .

Chemotherapy, especially with alkylating agents (cyclophosphamide, busulphan, chlorambucil, and nitrogen mustard), is associated with germ cell damage in the postpubertal ovary. The prepubertal ovary, on the other hand, is markedly resistant to chemotherapeutic damage of germ cells. The effect of combined oral contraceptive therapy during chemotherapy in adolescents remains controversial.

Survivors of childhood cancer who previously underwent abdominal or gonadal irradiation have an increased rate of spontaneous abortions. However, the incidence of congenital malformations is not increased in comparison with the general population. Patients who have evidence of premature ovarian failure may be candidates for assisted reproductive technology with the use of donor ova.

OVARIES

Neonatal and Pediatric Ovarian Cysts.

Most often the clinical manifestations of ovarian tumors are abdominal pain, mass, or both. Functional ovarian cysts rarely persist beyond the neonatal period. In adolescents, the most common neoplasm is the teratoma. The teratomas are usually benign, but malignant teratomas may occur. Calcification on abdominal roentgenogram is often a hallmark of a benign teratoma. During surgery, the opposite ovary should be evaluated, and if there is any question about the possibility of a neoplasm, a biopsy specimen should be obtained. Ovarian adenomas are the second most common benign tumor.

Although ovarian cancers are extremely uncommon in children, they are responsible for 1:500 ovarian malignancies. Ovarian cancers affect only 4% of women. With respect to germ cell tumors, the most common is the dysgerminoma, followed in incidence by malignant teratomas, endodermal sinus tumors, embryonal carcinomas, mixed cell neoplasms, and gonadoblastomas (see Chapter 495). Immature teratomas and endodermal sinus tumors are more aggressive malignancies than dysgerminomas and occur in a significantly higher proportion of younger girls (<10 yr of age). In this age group, 10-year survival rates were 73% for epithelial carcinomas, 44% for sex cord stromal tumors, 73% for dysgerminomas, 33% for malignant teratomas, 39% for endodermal sinus tumors, 25% for embryonal carcinomas, 30% for other germ cell neoplasms, and 100% for gonadoblastomas. Dysgerminomas usually are associated with XY gonadal dysgenesis; Y-DNA probes are important in their diagnosis. Tumor markers such as a-fetoprotein, carcinoembryonic antigen, and the antigen CA-125 are also used to assess ovarian malignancy (Table 545–1). The germ cell tumors are associated with positive alpha-fetoprotein, human chorionic gonadotropin (HCG), and chorioembryonic antigen.

Treatment consists of surgical excision followed by postoperative chemotherapy; radiotherapy is often necessary. Staging at the beginning of therapy is of the utmost importance. In many cases, a second-look procedure is indicated in order to decide about subsequent treatment of these neoplasms.

Embryonal Carcinoma.

This cancer accounts for 6% of pediatric ovarian neoplasms and 8% of all germ cell tumors. The patient presents with progressive increase in abdominal pain and distention. The embryonal cell carcinoma is highly malignant with an average age of detection between 13–15 yr. Overall, 60% of patients have endocrinologic signs and symptoms, which may include precocious pseudopuberty,

---

TABLE 545-1 -- **Serum Tumor Markers**

Marker	Associated Tumor
CA 125	Epithelial tumors (especially serous) Immature teratoma (rare)
Alpha-fetoprotein	Endodermal sinus tumors Embryonal carcinomas Mixed germ cell tumors Immature teratoma (rare) Polyembryoma (rare)

Human chorionic gonadotropins	Choriocarcinoma Embryonal carcinomas Mixed germ cell tumors Polyembryoma Dysgerminoma (rare)
Lactate dehydrogenase	Dysgerminoma Mixed germ cell tumors
Estradiol	Thecomas Adult granulosa cell tumors
Testosterone	Sertoli cell tumors Leydig (hilus) cell tumors
F9 embryoglycan	Embryonal carcinoma Yolk sac tumor Choriocarcinoma Immature teratoma
Inhibin	Granulosa–theca cell tumor
Müllerian inhibiting substance	Granulosa–theca cell tumor

abnormal vaginal bleeding, and hirsutism. Both HXG and alpha-fetoprotein are produced by embryonal cell carcinoma. *Treatment* involves unilateral salpingo-oophorectomy for stage I disease.

Endodermal Sinus Tumor.

These tumors are the most lethal of all ovarian cancers. The median age of presentation is 19 yr. The endodermal sinus tumor produces alpha-fetoprotein as a useful tumor marker. These tumors are radiosensitive. They may be treated surgically if they are stage I, for which a unilateral salpingo-oophorectomy is performed. Chemotherapy may be necessary independent of the stage of the disease.

Choriocarcinoma.

Primary choriocarcinoma of the ovary is extremely rare and often fatal; 0.6% of germ cell tumors are choriocarcinomas.

Mixed Germ Cell Tumor.

The frequency of mixed germ cell tumors is 4% of all ovarian neoplasms in children.

Sex Cord Stromal Tumor.

Sex cord stromal tumors comprise 5% of ovarian neoplasms, of which the granulosa cell tumor is the most common. Isosexual precocity and occasionally virilization may be observed in the juvenile variety. The characteristic histologic features include modular architecture, follicle formation, microcysts, cell necrosis, and increased mitotic activity.

Sertoli–Leydig Cell Tumor.

This tumor is also a sex cord stromal tumor and accounts for 2% of pediatric ovarian tumors. Sertoli–Leydig cell tumors are rare in prepubertal girls. The patient presents with evidence of virilization. *Treatment* includes unilateral salpingo-oophorectomy for stage I disease.

Ovarian Follicular Cysts.

These cysts occur from birth to puberty and usually disappear spontaneously. On ultrasound examination, the cyst usually presents as a nonechogenic area, frequently larger than 20?mm at its greatest diameter; diffuse swelling of the ovarian parenchyma and follicular enlargement of the cortical zone are also noted.

Polycystic Ovarian Syndrome (PCOS).

This syndrome presents with menstrual dysfunction and signs and symptoms of androgen excess often at the time of puberty. The menstrual irregularity can range from amenorrhea to oligomenorrhea. See Chapter 544 .

Functional and Hemorrhagic Ovarian Cysts.

These cysts are an integral part of follicular development during the menstrual cycle. On occasion a cyst may persist and increase in diameter. Following ovulation, it is termed a *corpus hemorrhagicum*. These are often symptomatic and best evaluated by ultrasonography. Expectant management for a presumed functional cyst is appropriate, with follow-up ultrasound imaging. Monophasic oral contraceptives can facilitate suppression of functional cysts.

Ovarian Torsion.

Torsion of an adnexum is a complication that should always be considered in the differential diagnosis of ovarian tumors or abdominal pain in a female patient; prompt surgical intervention is necessary. Torsion often presents with intermittent sharp abdominal pain that, in many cases, radiates down the ipsilateral extremity. Bilateral ovarian torsion also may occur in infancy. When unilateral torsion is diagnosed, oophoropexy (plication) of the contralateral adnexa may be indicated.

The incidence of ovarian torsion in one series was 25% (16 of 63 benign ovarian masses). Color Doppler flow studies can facilitate the diagnosis. Adnexal torsion can often be evaluated and managed with the use of Doppler flow studies and laparoscopy. The underlying cause is usually an associated ovarian cyst or neoplasm. Recovery of ovarian function after laparoscopic detorsion has been reported with identification of normal follicle development on ultrasonography. Therefore, it is recommended that adnexal torsion be managed conservatively.

Autoamputation of the Ovary.

This entity presents as a small, calcified, free-floating mass associated with absent adnexa. The child may be asymptomatic, and ultrasonography is often helpful in establishing the diagnosis. It has been hypothesized that antenatal or subclinical ovarian torsion leads to necrosis, calcification, and separation of the adnexa from its blood supply.

Juvenile Granulosa Cell Tumors of the Ovary (JGCT).

JGCT account for 1–2% of all ovarian tumors. The median age of presentation is 7.6 yr, with a range of 6?mo–17.5 yr. The majority of patients have abdominal distention and sexual precocity. Patients appear to have increasingly better prognosis with the advent of multidrug chemotherapy, including cisplatin-based regimens. However, neurotoxicity, especially ototoxicity, and bone marrow depression are serious complications.

CERVIX

The prevalence of dysplasia and carcinoma in situ is 18.8/1,000 for those 15–19 yr of age, and biopsy-proven cases of all grades of cervical intraepithelial neoplasia (CIN) in the teenage population have a prevalence of 13.3/1,000. The Bethesda Classification System with the Papanicolaou (Pap) smear is widely used for diagnosis. The overall frequency of abnormal Pap smear results in the adolescent population is 3.8%, and 1% of all abnormal Pap smears are associated with CIN. Papillomavirus infection (Chapter 243) and altered vaginal flora are consistent findings in patients with CIN. Abnormal Pap smear results in adolescents also correlate with significant CIN and should be followed up with a biopsy. Colposcopic examination is essential when CIN is diagnosed in an adolescent. Other pathologic abnormalities of the cervix include cervical polyps and mixed mesodermal tumors. The latter may represent a mixed, heterologous, or homologous sarcoma of the uterine cervix.

UTERUS (BENIGN AND MALIGNANT TUMORS OF THE UTERINE CORPUS)

Adenocarcinoma of the corpus is rare in children and adolescents. Vaginal bleeding not associated with sexual precocity is a frequent presenting sign. Treatment consists of hysterectomy,

with removal of the ovaries, followed by adjunctive radiotherapy or chemotherapy or both, depending on the operative findings. Mixed mesodermal tumors and leiomyomas of the uterus should be included in the differential diagnosis of a pelvic mass in an adolescent. Leiomyosarcoma, although extremely rare, has also been noted in an adolescent; the presentation is variable, but abnormal vaginal bleeding usually is present.

VAGINA

Gartner duct (mesonephric) cyst is a common vaginal wall abnormality. It usually is an incidental finding and requires no specific therapy. In sexually active patients, excision may be necessary if there is associated dyspareunia. Paramesonephric (müllerian) duct cysts often become symptomatic at menarche when the cavity fills with menstrual blood. Women who were exposed to diethylstilbestrol (DES) in utero have a high incidence of adenosis of the vagina and cervix. These patients also have potential reproductive abnormalities, including infertility, habitual abortion, and tubal and uterine cavity abnormalities. Clear cell adenocarcinoma of the vagina and cervix is a rare sequela of DES exposure in utero.

Sarcoma botryoides, a vaginal carcinoma that occurs primarily in pediatric patients, is best treated by surgical excision. Chemotherapy is usually administered postoperatively. Any questionable vulvar lesion should be submitted for histologic examination. Liposarcoma of the vulva has been reported in a 15 yr old girl. Malignant melanoma of the vulva has also been described in a 14 yr old patient.

Chapter 546 - Vulvovaginal and Müllerian Anomalies

Embryology.

The uterus is formed by fusion of the caudal elements of the müllerian ducts, a process that occurs at 8 wk of gestation. The fusion begins from the caudal end (Müller tubercle) and is completed at the upper level of the fundus. A median septum is present until the end of the 1st trimester of gestation.

The vagina is formed from the terminal portion of the utero-vaginal canal (Müller tubercle). The tissue is of combined urogenital and müllerian duct origin and is known as the vaginal epithelial plate. Bilateral evaginations of the vaginal epithelial plate encircle the caudal aspect and form the uterine canal. Canalization of the vaginal plate occurs and proceeds in a caudal direction to form the vagina. The process elongates the vaginal structure, leaving the cranial two thirds of müllerian origin and the caudal one third of urogenital origin.

The paramesonephric system is responsible for müllerian tract development. Failure of lateral fusion or lack of resorption of the vertical midline septum results in a müllerian anomaly. Because of the intimate anatomic and embryologic development of the urinary and genital systems, the urinary tract is often also affected; skeletal defects, including spina bifida occulta, occur as well. Common müllerian duct anomalies and associated heritable disorders are presented in Tables 546–1 and 546–2 .

Imperforate Hymen.

The patient presents with primary amenorrhea; secondary sex characteristics are normal. The imperforate hymen requires surgical intervention. The outflow tract obstruction when relieved should include evaluation of the vaginal canal for any other defects.

Congenital Absence of the Vagina (Mayer-Rokitansky-Küster-Hauser Syndrome).

The incidence is reported as 1/4,000 to 1/5,000 births. The etiology is unknown. Vaginal agenesis is characterized by primary amenorrhea, normal vulva, duplication anomaly of the uterus, attenuated fallopian tubes, normal ovaries, normal female karyotype and phenotype, and associated anomalies (most frequently renal and skeletal). The anomaly is often discovered in adolescents. Absence of the vagina has significant anatomic, physiologic, and psychologic implications for the patient and family.

TABLE 546-1 -- **Common Müllerian Anomalies**

Hydrocolpos	Accumulation of mucus or nonsanguineous fluid in the vagina
Hemihematometra	Atretic segment of vagina with menstrual fluid accumulation
Hydrosalpinx	Accumulation of serous fluid in the fallopian tube, often an end result of pyosalpinx
Didelphic uterus	Two cervices, each associated with one uterine horn
Bicornuate uterus	One cervix associated with two uterine horns
Unicornuate uterus	Result of failure of one müllerian duct to descend

Treatment is usually delayed until the patient is ready to be sexually active. The nonsurgical approach includes use of frank dilators to create a functional vagina. There is also a combined laparoscopic vulvar procedure in which an olive-tip with suture attached is placed at the introital area and sutures are brought up through the space of Retzius. Progressive increase in tension results in development of a functional vagina. Alternatively, surgical intervention with a McIndoe procedure involving a split-thickness skin graft placed in the vagina area has proved to be a successful approach.

Lesions involving other organ systems occur in association with the Mayer-Rokitansky-Küster-Hauser syndrome. The most common are urinary tract anomalies primarily involving unilateral absence of a kidney or a ureter (27%) and skeletal anomalies (12%), which primarily involve vertebral development.

Incomplete Vertical Fusion of the Vagina.

Transverse and longitudinal vaginal septa represent failure of complete canalization of the vagina. Not uncommonly, the patient presents with amenorrhea and cyclical pain, which is a result of cryptomenorrhea. Müllerian agenesis must be differentiated from androgen insensitivity (testicular feminization); serum testosterone levels are usually in the male range with the latter. Müllerian agenesis, with a reported incidence of 1/50,000 to 1/20,000, is more common than androgen insensitivity and is second in frequency to gonadal dysgenesis as a cause of primary amenorrhea.

Renal anomalies are noted in 34% and skeletal anomalies in 12% of patients. Unilateral renal agenesis occurs in 15% of patients. The most frequent skeletal anomalies are vertebral. Klippel-Feil syndrome has been associated with müllerian agenesis. Patients usually have a normal female karyotype (46 XX), but autosomal translocation of chromosomes 12q and 14q also occurs. Affected siblings have been reported, as well as families with variable expression of defects in müllerian, renal, and skeletal systems.

A pelvic ultrasound examination is helpful in defining the anomaly; computed tomographic scanning and magnetic resonance imaging provide increased detail. Laparoscopy is usually reserved for evaluating a pelvic mass and associated abnormalities. Radiologic or sonographic evaluation is indicated to identify associated anomalies. A karyotype should be obtained.

TABLE 546-2 -- **Heritable Disorders Associated with Müllerian Anomalies**

Mode of Inheritance	Disorder	Associated Müllerian Defect
Autosomal dominant	Camptobrachydactyly Hand-foot-genital	Longitudinal vaginal septa Incomplete müllerian fusion
Autosomal recessive	Kaufman-McCusick Johanson-Blizzard Renal-genital–middle ear anomalies Fraser's syndrome Uterine hernia syndrome	Transverse vaginal septa Longitudinal vaginal septa Vaginal atresia Incomplete müllerian fusion Persistent müllerian duct derivatives
Polygenic/multifactorial	Mayer-Rokitansky-Küster-Hauser syndrome	Müllerian aplasia
X linked	Uterine hernia syndrome	Persistent müllerian duct derivatives

From Shulman L, Elias S: Developmental abnormalities of the female reproductive tract: Pathogenesis and nosology. Adolesc Pediatr Gynecol 1988;1:232.

Vaginoplasty is best deferred until a patient has matured and should be supported by counseling for both patient and family. The McIndoe procedure involves the use of a skin graft, usually from the buttocks, to create a vagina after appropriate dissection of the vulvovaginal area. The artificial vaginal epithelium changes cytologically to an almost normal appearing vaginal mucosa. Other reconstructive procedures have included fasciocutaneous flaps. Various dilatation procedures may also result in an increased vaginal size, which ultimately permits intercourse. Squamous cell carcinoma of the reconstructed vagina has been reported and appears to be related to the type of tissue transplanted. Radiotherapy is usually the primary method of treatment for this squamous cell carcinoma.

Transverse Vaginal Septa.

The incidence of this lesion is approximately 1/80,000 females. The patient usually presents with amenorrhea, which may be associated with cyclic pelvic pain, a pelvic mass, and cryptomenorrhea. Although usually asymptomatic until puberty, hydrometrocolpos may occur in children. Transverse vaginal septa may be associated with other congenital anomalies, although this occurs less often than with müllerian agenesis. The most common site of the septum is between the middle and upper thirds of the vagina. These patients have a functional uterus, although their fertility is often compromised; 47% of affected females in one retrospective series had spontaneous abortions. The prognosis is worse for higher obstructions. There is also an increased incidence of endometriosis secondary to retrograde menstruation.

Evaluation of transverse vaginal septa includes careful pelvic examination and often pelvic imaging to delineate the anatomic abnormalities. Treatment is surgical resection of the obstruction from below. Anastomosis of the upper and lower segments should be attempted, if at all possible, to prevent stenosis. A skin graft may be necessary. A Lucite stent is often placed in the vagina to maintain patency.

Disorders of Lateral Fusion.

These include a number of anatomic variations of nonobstructive longitudinal septum as well as the obstructed hemivagina. The latter may be associated with a didelphic uterus and often with a pelvic mass, which represents retrograde menstruation associated with the occluded hemivagina. Menses, often cyclic, indicates an unobstructed outflow tract from one of the uterine horns.

Uterine Abnormalities.

The incidence of uterine anomalies ranges from 1/100 to 1/1,000. Anomalous development of the uterine

cavity may have varied clinical manifestations. Patients may present with primary amenorrhea or with irregular or even regular menses. There may be an asymptomatic pelvic mass or dysmenorrhea. In adolescents and adults, pregnancy wastage and infertility may cause the first suspicion of a uterine anomaly.

Diagnosis should include a pelvic ultrasound examination, renal tract assessment, and skeletal inspection for anomalies. Karyotyping and diagnostic laparoscopy may be necessary, depending on the presentation and laboratory assessment.

Treatment depends on the specific anomaly, and surgical repair to date has included Strassman metroplasty, Jones “wedge” metroplasty, and Tompkins metroplasty or hysteroscopic resection. The obstructions to the outflow tract must also be relieved; this may necessitate creation of a vaginal window or excision of a hemivagina. Retrograde menstruation in a uterine horn must also be evaluated and, if present, appropriate surgical correction provided.

Congenital Atresia of the Uterine Cervix.

This extremely rare anomaly often presents at puberty with cryptomenorrhea, amenorrhea, and pelvic pain. It is associated with significant renal anomalies in 5–10% of patients. On examination, complete absence of a cervix but a palpable uterus is found. Pelvic imaging is helpful in defining the abnormality. Treatment may include laparotomy to create a uterovaginal fistula. If this is impossible, a hysterectomy may be necessary. Other associated anomalies include mesonephric cysts, which are remnants of the wolffian duct, incomplete reduplication of internal genitalia (e.g., didelphic uterus), and unilateral renal aplasia. In addition, gastrointestinal (42.9%), respiratory (47.6%), central nervous system (28.6%), cardiovascular (38.1%), and musculoskeletal abnormalities (33.3%) have been reported with this abnormality.

Complete Vulvar Duplication.

This rare congenital anomaly presents in infancy and consists of two vulvas, vaginas, and bladders, a didelphic uterus, a single rectum and anus, and two renal systems.

Labial Hypertrophy.

Elongation of the labia minora may be present at birth. This usually is of no consequence, but surgical revision may be indicated if there are symptoms of discomfort or bulging is noted when wearing tight fitting garments.

Clitoral Abnormalities.

Agenesis of the clitoris is rare. Clitoral duplication occurs, often associated with pelvic organ abnormalities, including agenesis of other genital tract structures and bladder exstrophy.

Hymenal Abnormalities.

An imperforate hymen may be present in pediatric patients and is often associated with mucocolpos; hydrometrocolpos may also be noted. Other hymenal abnormalities include cribriform or stenotic hymen.

Cloacal Anomalies.

These lesions represent a common urogenital sinus into which both urethral and anal orifices exit. The single opening (cloaca) requires surgical correction.

MANAGEMENT OF EMERGENCIES ASSOCIATED WITH CONGENITAL MALFORMATIONS OF THE FEMALE GENITAL TRACT

The clinical manifestations of müllerian anomalies are varied. There may be a pelvic mass, which may or may not be associated with symptoms. A vaginal bulging mass or hemivagina is indicative of complete or partial outflow tract obstruction. An adolescent may present with pelvic pain, either in association with primary amenorrhea or several months after the onset of menarche. Patients also may be asymptomatic until there is evidence of repeat pregnancy wastage. When a presentation is acutely symptomatic, emergency management may be required.

Outflow Tract Obstruction

Obstruction may result from a number of distinct anomalies including the imperforate hymen, transverse vaginal septum, and noncommunicating rudimentary horn. As menstrual fluid accumulates proximal to the obstruction, the resulting hematocolpos, hematometra, or hematocolpometra causes cyclic pain or a pelvic mass. These obstructions are best considered according to the location of the obstruction.

Distal Vagina/Imperforate Hymen.

This is the most common obstructive anomaly, and familial occurrences are reported. In the newborn period and early infancy, it may be diagnosed by a bulging membrane due to a mucocolpos from maternal estrogen stimulation. If not noted at this time, it is often not diagnosed until puberty, when menstrual fluid accumulates. The clinical manifestations often are a bulging blue-black membrane, pain, primary amenorrhea, and normal secondary sex characteristics. Depending on the circumstance, patients may have cyclic abdominal pain or a pelvic mass.

Treatment requires incision/resection of the membrane, thus relieving the outflow

tract obstruction. Repair should be done at time of diagnosis, if a patient is symptomatic. Although the lesion may be repaired anytime during infancy, childhood, or adolescence, surgery is facilitated by estrogen stimulation and thus ideally performed in adolescence.

Proximal or Midvaginal Transverse Septum.

Vertical fusion defects can result in a transverse septum, which may be imperforate and associated with hematocolpos or hematometra in adolescents, or mucocolpos in children. If there is a small, pinpoint aperture, fluid accumulates in the vagina. As with an imperforate hymen, a mass may be present. The vagina appears short or blind ended. The approach to resection of the septum depends on the presence or absence of an opening. In the presence of an opening, cannulation should be attempted with resection of the septum. Postoperatively, a vaginal stent may be necessary.

Rudimentary Horns.

This emergency results from the presence of a horn with a functional endometrium and outflow tract obstruction. As with other types of outflow tract obstruction, severe lower abdominal pain with a pelvic mass is the primary clinical manifestation. In contrast to other forms of outflow tract obstruction, however, primary amenorrhea is usually not present because the opposite horn is unlikely to be obstructed. Asymptomatic rupture of a rudimentary horn in an adult has occurred.

Ultrasonography is indicated for visualizing the rudimentary horn. An intravenous pyelogram (IVP) or renal ultrasonography also should be obtained because of associated anomalies. If there is evidence of a functional endometrium, surgical extirpation is recommended.

Rudimentary Horn Pregnancy

This occurs in 1/40,000 pregnancies and 1/5,000–15,000 ectopic pregnancies. It may be a result of a fibromuscular or fibrous band connecting the unicornuate uterus and the rudimentary horn, but 80–85% of cases are noncommunicating. The latter is probably the result of transperitoneal migration of either sperm or the fertilized ovum. In contrast to tubal pregnancies, rudimentary horn pregnancies are often not detected until the second trimester. Because of the greater muscle wall thickness of most horns, rupture typically occurs later than in tubal gestation.

Most cases are diagnosed only after rupture occurs, when patients have acute abdominal pain and peritoneal signs and are often in shock. When rupture occurs, intraperitoneal hemorrhage may be massive and life threatening and requires immediate

surgical intervention. Maternal mortality is about 5%, with 90% of this occurring within 10–15?min after rupture. Fetal demise occurs in 98%.

Before rupture, diagnosis of a rudimentary horn pregnancy may be difficult. It should be suspected in any gravida with a known rudimentary horn, and these patients should be closely monitored until an intrauterine pregnancy has been documented. In those who have not been previously identified as having a rudimentary horn, findings on early pelvic examination are similar to findings of tubal ectopic pregnancy and include deviation of the cervix to one side with an adnexal mass on the opposite side. Ultrasound findings before rupture include an extrauterine gestational sac and placenta within the horn next to a slightly enlarged uterus.

Treatment consists of surgical resection of the rudimentary horn.

Acute Urinary Retention

Outflow tract obstruction resulting in accumulation of fluid in the vagina or uterus may cause urinary retention as a result of mucocolpos in the first years of life or hematocolpos, hematometra, or hematocolpometra during the pubertal years. The retained fluid in the vagina compresses the urethra, and this is aggravated when the fluid-filled uterus applies pressure on the posterior wall of the bladder and changes the angle of the urethra. Pressure on the sacral plexus from the distended vagina may also be contributory.

The usual clinical manifestations in adolescents are lower abdominal pain and the inability to void. There also may be hesitancy and incomplete voiding for several days before presentation. Adolescents generally have primary amenorrhea, a history of cyclic lower abdominal pain, and a pelvic mass. However, if the obstruction is unilateral, as with a noncommunicating rudimentary horn or an obstructed hemivagina, the patient may have normal menses.

Temporary but immediate relief can be provided by urethral catheterization. If resistance occurs within an appropriately sized rubber catheter, a pediatric feeding tube may be used, or if necessary, a spinal needle may be passed suprapubically to empty the bladder. Urine should be sent for urinalysis and culture because urinary stasis promotes infection. Once the acute condition has been treated, the underlying problems and the obstructing mass should be appropriately evaluated. Urinary tract infections also have been associated with müllerian anomalies. This may result from renal anomalies with vesicourethral reflux, or it may precede retention as a result of vaginal outflow obstruction. Antibiotic treatment is indicated.

Acute Genital Trauma in the Premenarchal Girl

Acute genital trauma in children can present as superficial genital lacerations and abrasions that do not have active bleeding and may be merely observed. Active bleeding following trauma in the genital area merits appropriate evaluation, which usually includes examination under anesthesia with surgical repair. Forensic studies may be indicated, if there is any suspicion of sexual abuse. Application of topical estrogen cream appears to facilitate the healing process in the vulvovaginal area and clinicians should consider this following surgical intervention.

Chapter 547 - Athletic Gynecologic Problems

The most common gynecologic problem in female athletes is menstrual aberration, usually manifested as amenorrhea or oligomenorrhea. Female adolescents who participate in strenuous training have low serum estradiol levels and are predisposed to bone demineralization. Puberty and menarche may be delayed.

Endogenous opiates within the hypothalamus may inhibit gonadotropin-releasing hormone neurons and thus affect luteinizing hormone secretion and reproductive function. There is also an increase in corticotropin secretion. In addition, a change in body composition and weight loss is involved in the menstrual abnormality. Amenorrheic runners tend to have less body fat than eumenorrheic runners, and menarche is delayed approximately 3 yr in ballet dancers (in comparison with nonathletic adolescents) preparing for a professional career. Delayed puberty in association with endurance training does not result in significant alteration of follicle-stimulating hormone and luteinizing hormone levels. It is important to assess nutritional status and other potential causes before delayed puberty is attributed to athletic activities.

The triad of disordered eating, amenorrhea, and osteoporosis is a common clinical entity among female athletes. Educational efforts, especially among adolescents, should focus on these potential problems and how to avoid them. Appropriate weight maintenance, dietary habits, and psychological factors should be addressed.

Chapter 548 - Special Gynecologic Needs

Mentally Handicapped Children.

Perineal hygiene is a major problem for severely mentally handicapped pediatric or adolescent patients. Initially, an adequate gynecologic examination and Papanicolaou smear should be provided. A number of medical approaches should then be considered to suppress menses. Depo-medroxyprogesterone acetate, usually prescribed at a dose of 150?mg, may be injected intramuscularly every 3 mo. Alternatively, oral contraceptives do not produce amenorrhea but result in a marked decrease in the quantity of menstrual flow. Before hysterectomy, there should be a thorough discussion with parents or custodians after a trial of medical treatment has not been successful. An ethics advisory committee should be consulted to aid in decisions about sterilizing mentally handicapped patients (see also Chapters 2 and 37).

The problem of sexual abuse of the mentally handicapped child continues to be a challenge for both clinicians and those providing care for these children. Every effort should be made to prevent sexual abuse of mentally or physically handicapped girls. Contraception may be prescribed for patients at increased risk for pregnancy. This does not always require an initial pelvic examination. Sonography has been utilized in special circumstances to evaluate the pelvic organs prior to initiating contraceptive therapy.

Premature Ovarian Failure in Association with Chemotherapy and/or Radiation Therapy.

The incidence of premature ovarian failure has increased with the increased survival of children and adolescent patients having neoplasms. Hormone replacement therapy in an approach similar to that of menopause, i.e., physiologic estrogen replacement therapy with the addition of progestins, provides the patient with secondary sex characteristics as well as regular menses.

Chapter 549 - Gynecologic Imaging

A transabdominal ultrasonic approach with a distended bladder serving as an imaging window facilitates identification of the uterus and the ovaries; bladder distention with urine displaces gas-filled bowel loops out of the pelvis and enhances imaging. A 7.5- or 5-MHz transducer is usually used, especially with larger children and teenagers. Ultrasonography is a key screening tool, enabling appropriate diagnosis in patients presenting with ambiguous genitalia, ovarian or uterine masses, primary amenorrhea, and abdominal or pelvic pain. Normal values are listed in Table 549–1 .

Pelvic masses can be identified at any age. Ovarian cysts and hydrocolpos or hydrometrocolpos are the most common abnormalities noted in neonates. Hydrocolpos is defined as dilatation of the vagina, which usually is associated with accumulation of serous fluid or urine (if there is a urogenital sinus). Hydrometrocolpos causes dilatation of both the uterus and the vagina. It may also be associated with vaginal or cervical atresia, stenosis, or an imperforate hymen. Most large ovarian cysts (simple cystic) in children may be safely observed with serial pelvic ultrasonography and tend to decrease in size or completely resolve. A solid mass requires a tissue diagnosis.

Magnetic resonance imaging is useful in evaluating müllerian duct anomalies. It should be used in conjunction with

Part 25 - The Endocrine System

Section 1 - *Disorders of the Hypothalamus and Pituitary Gland*

Chapter 550 - Hormones of the Hypothalamus and Pituitary

John S. Parks

The anterior pituitary gland originates from the Rathke pouch as an invagination of the oral ectoderm. It then detaches from the oral epithelium and becomes an individual structure of rapidly proliferating cells. Persistent remnants of the original connection between the Rathke pouch and the oral cavity can develop into craniopharyngiomas, which are the most common type of tumor in this area. Five cell types in the anterior pituitary produce six peptide hormones. Somatotropes produce growth hormone (GH), lactotropes produce prolactin (PRL), thyrotropes make thyroid-stimulating hormone (TSH), corticotropes express pro-opiomelanocortin (POMC), the precursor of corticotropin (adrenocorticotropic hormone [ACTH]), and gonadotropes express both luteinizing hormone (LH) and follicle-stimulating hormone (FSH).

A series of sequentially expressed transcriptional activation factors directs the differentiation and proliferation of anterior pituitary cell types. These proteins are members of a large family of DNA-binding proteins resembling homeobox genes. The consequences of mutations in several of these genes are evident in human forms of multiple pituitary hormone deficiency.

The HESX1 gene is expressed in precursors of all five cell types early in development, at embryonic day 8.5 (e8.5) in the mouse. It is not expressed after day e13.5. Pituitary OTX or Ptx-1 is also expressed early. This protein is capable of activating transcription from the POMC, GH, and PRL promoters as well as from the promoter of the a-glycoprotein subunit (a-GSU) that is common to LH, FSH, and TSH. In vitro, it can also activate the ß-LH and ß-FSH subunits. It acts cooperatively with the transcription factor POU1F1 (formerly termed PIT1) in activation of transcription from the GH and PRL promoters. Ptx-1 appears to be necessary for expression of the next transcription factor in the cascade, termed LHX3. The protein encoded by LHX3 appears by day e9.5. It activates the a-GSU promoter and acts synergistically with POU1F1 to increase transcription from the PRL, ß-TSH, and POU1F1 promoters. Targeted disruption of this gene in the mouse produces a phenotype of hypopituitarism in which the Rathke pouch develops normally, but the anterior and intermediate lobes of the pituitary fail to develop. The Ptx-2 gene, also known as the Rieg1 gene, is expressed from day e11 into adult life. Its DNA-binding domain differs from that of Ptx-1 by only 2 of 60 amino acids. The Ptx-2 protein is also found in developing eye, tongue, kidney, testis, and umbilicus. Expression of the "Prophet of Pit-1" or PROP1 gene begins at day e10.5 and is downregulated by day e14.5. This protein is found in the nuclei of somatotropes, lactotropes, and thyrotropes. Its role includes turning off HESX3 and turning on POU1F1. The POU1F1 (POU-homeodomain factor 1) appears at day e14.5 and is necessary for emergence of somatotropes, lactotropes, and a definitive population of thyrotropes. This protein persists in the mature pituitary and is involved in activation of GH, PRL, and ß-TSH expression.

Anterior Lobe Hormones.

The protein hormones produced by the anterior pituitary act on other endocrine glands and on certain body cells to affect almost every organ. Anterior pituitary cells are themselves controlled by neuropeptide-releasing and release-inhibiting hormones that are produced by hypothalamic neurons, secreted into the capillaries of the median eminence, and carried by portal veins to the anterior pituitary. Many conditions formerly classified as pituitary in origin are caused by hypothalamic defects.

Human GH is a protein with 191 amino acids. Its gene (GH1) is the first in a cluster of five closely related genes on the long arm of chromosome 17 (q22-24). The four other genes have greater than 90% sequence identity with the GH1 gene. They consist of the CS1 and CS2 genes, which encode the same human chorionic somatomammotropin (hCS) protein, a placental growth hormone gene (GH2), and a pseudogene (CSP). Syncytiotrophoblastic cells of the fetal placenta produce large quantities of hCS, and placental GH replaces pituitary GH in the maternal circulation after 20 wk of gestation. When the fetal genome lacks the CS1, CS2, GH2, and CSP genes, hCS and placental GH are absent, but fetal growth and postpartum lactation are normal.

The GH1 gene is expressed in pituitary somatotropes under the control of three hypothalamic hormones. Growth hormone-releasing hormone (GHRH) stimulates and somatostatin inhibits GH release. Alternating secretion of GHRH and somatostatin accounts for the rhythmic secretion of GH. Peaks of GH occur when

peaks of GHRH coincide with troughs of somatostatin. The secretion of GH is pulsatile, with the highest peaks occurring with sleep. A second stimulatory system, parallel to that involving the GHRH receptor, is activated by ghrelin. Ghrelin is produced in the arcuate nucleus of the hypothalamus and in much greater quantities by the stomach. GH secretion may be influenced by ghrelin levels in the hypothalamic-pituitary portal circulation and the systemic circulation. Fasting stimulates and feeding inhibits ghrelin release into the systemic circulation. Intraventricular injection of ghrelin increases feeding and weight gain in rats.

The three molecular species of GHRH contain 37, 40, or 44 amino acids. A fully active 29-amino acid synthetic GHRH is available as a diagnostic agent and for treatment of GH deficiency secondary to GHRH deficiency. Somatostatin exists in 14- and 28-amino acid forms. Somatostatin production is not limited to the hypothalamus. It also acts through autocrine and paracrine mechanisms in the islets of Langerhans and in the gastrointestinal tract. Somatostatin inhibits secretion of

insulin, glucagon, secretin, gastrin, vasoactive intestinal peptide (VIP), GH, and thyrotropin. In the pancreatic islets, it is localized to the D cells. Somatostatin-secreting pancreatic tumors (somatostatinomas) occur in adults. A potent, long-acting somatostatin analog, octreotide, which inhibits GH preferentially over insulin, is available to treat patients with GH-secreting tumors. It is also useful in managing patients with gastrinomas, insulinomas, glucagonomas, VIPomas, and carcinoid tumors (see Chapters 81 and 326). ^{123}I-labeled octreotide appears to be useful in localizing somatostatin receptor-positive tumors and their metastases. Ghrelin has an unusual structure. It consists of 28 amino acids and the third amino acid, a serine, is octanoylated. This octanoyl group is essential for physiologic activity.

GH acts through binding to receptor molecules on the surface of target cells. The GH receptor is a single-chain molecule of 620 amino acids. It has an extracellular domain, a single membrane-spanning domain, and a cytoplasmic domain. Proteolytically cleaved fragments of the extracellular domain circulate in plasma and act as a GH-binding protein. As in other members of the cytokine receptor family, the cytoplasmic domain of the GH receptor lacks intrinsic kinase activity; instead, GH binding induces receptor dimerization and activation of a receptor-associated Janus kinase (Jak2). Phosphorylation of the kinase and other protein substrates initiates a series of events that leads to alterations in nuclear gene transcription.

The mitogenic actions of GH are mediated through increases in the synthesis of insulin-like growth factor-I (IGF-I), formerly named somatomedin C, a single-chain peptide with 70 amino acids coded for by a gene on the long arm of chromosome 12. IGF-I has considerable homology to insulin. Circulating IGF-I is synthesized primarily in the liver and formed locally in mesodermal and ectodermal cells, particularly in the growth plate of children, where its effect is exerted by paracrine or autocrine mechanisms. Circulating levels of IGF-I are related to blood levels of GH to a large extent, except in the fetus and during the neonatal period. IGF-I circulates bound to several different binding proteins; the major one is a 150-kd complex (IGF-BP3), which is decreased in GH-deficient children but is in the normal range in children

who are short for other reasons. Human recombinant IGF-I may have therapeutic potential in conditions characterized by end organ resistance to GH. Examples include Laron syndrome, a state of resistance to GH caused by mutations in the GH receptor, and resistance caused by the development of antibodies to administered GH. IGF-II is a single-chain protein with 67 amino acids that is coded for by a gene on the short arm of chromosome 11. It has homology to IGF-I, but much less is known about its physiologic roles, although it appears to be an important mitogen in bone cells, where it occurs in a concentration many times higher than that of IGF-I.

Several disorders of growth are caused by abnormalities of the genes that code for the GHRH receptor, HESX1, POU1F1, PROP1, LHX3, GH1, the GH receptor, and IGF-I.

Prolactin is composed of 199 amino acids, and its gene is located on chromosome 6. The major prolactin-inhibiting factor is dopamine; medications that disrupt hypothalamic dopaminergic pathways result in increased serum levels of prolactin. Serum levels of prolactin are increased after administration of thyrotropin-releasing hormone (TRH), in states of primary hypothyroidism, and after disruption of the pituitary stalk, as may occur in children with craniopharyngioma. Levels are decreased by destruction of the pituitary and by mutations in PROP1 and POU1F1, which interfere with the embryonic development of lactotropes.

The main established role for prolactin is the initiation and maintenance of lactation. Concentrations in amniotic fluid are 10–100 times the levels in maternal or fetal serum. The major source of amniotic prolactin appears to be the decidua. Mean serum levels in children and in fasting adults of both sexes are about 5–20?µg/L, but levels in the fetus and in neonates during the 1st wk of life are usually higher than 200?µg/L.

TSH consists of two glycoprotein chains linked by hydrogen bonding. The a-chain is identical to that found in FSH, LH, and chorionic gonadotropin (hCG). The ß-chain is unique in each of these hormones and confers specificity. The gene for the a-chain has been mapped on chromosome 6, that for the a-chain of TSH on chromosome 1, and those for the ß-chains for LH and hCG on chromosome 19. TSH increases iodine uptake, iodide clearance from the plasma, iodotyrosine and iodothyronine formation, thyroglobulin proteolysis, and release of thyroxine (T_4) and triiodothyronine (T_3) from the thyroid. Most of the effects of TSH are mediated by cyclic adenosine monophosphate. Deficiency of TSH results in inactivity and atrophy of the thyroid, and excess results in hypertrophy and hyperplasia.

TRH is a tripeptide ([pyro] Glu-His-Pro-NH2). Thyroxine and triiodothyronine inhibit TSH secretion by blocking the action of TRH on the pituitary cell. TRH also stimulates the release of prolactin in both sexes. Synthetic TRH is useful for testing pituitary reserves of TSH and prolactin.

ACTH is derived by proteolytic cleavage from a large precursor glycoprotein product of the pituitary gland called POMC. Cleavage of POMC yields ACTH, a single chain of 39 amino acids, and ß-lipotropin (ß-LPH), a 91-amino acid glycoprotein. Further cleavage of ACTH and ß-LPH in the pituitary yields yet other hormonal products. The a-melanocyte-stimulating hormone is identical to the first 13 amino acids of ACTH but has no corticotropin activity. Cleavage of ß-LPH results in neurotropic peptides

with morphinomimetic activity (fragment 61–91 is ß-endorphin), and ß-melanocyte-stimulating hormone consists of a 17-amino acid fragment of ß-LPH.

ACTH acts primarily on the adrenal cortex. It produces changes in structure, chemical composition, enzymatic activity, and release of corticosteroid hormones. ACTH release has a diurnal rhythm. The level is lowest between 10 pm and 2 am, with peak levels reached about 8 am. Levels of ß-LPH and ß-endorphin are elevated in patients with increased levels of ACTH. It appears that ACTH rather than MSH is the principal pigmentary hormone in humans.

POMC peptides are also produced in nonpituitary tissues. In the testis, some peptides act as autocrine regulators of androgen-secreting Leydig cells, and others may potentiate or oppose the action of FSH on Sertoli cells.

Secretion of ACTH, ß-endorphin, and other POMC-related peptides is regulated by corticotropin-releasing hormone (CRH). CRH is a 41-amino acid peptide found predominantly in the median eminence but also in other areas of the brain and in tissues outside the brain, particularly the placenta. During pregnancy, levels of CRH increase several hundred-fold, increase further during labor and delivery, and then decrease to nonpregnant levels within 24?hr. Its source is probably the placenta, which contains the peptide and its mRNA. Synthetic CRH is available for diagnostic use and it is particularly useful in differentiating the different forms of Cushing syndrome.

Gonadotropic hormones include two glycoproteins, LH and FSH. They contain the same a subunit as TSH and distinct ß subunits. Receptors for FSH on the ovarian granulosa cells and on testicular Sertoli cells mediate FSH stimulation of follicular development in the ovary and of gametogenesis in the testis. On binding to specific receptors on ovarian theca cells and testicular Leydig cells, LH promotes luteinization of the ovary and Leydig cell function of the testis. The receptors for LH and FSH belong to a class of receptors with seven membrane-spanning protein domains. Receptor occupancy activates adenylyl cyclase through mediation of G proteins.

Luteinizing hormone-releasing hormone, a decapeptide, has been isolated, synthesized, and widely used in clinical studies. Because it leads to the release of LH and FSH from the same

gonadotropic cells, it appears that there is only one gonadotropin- releasing hormone.

Secretion of LH is inhibited by androgens and estrogens, and secretion of FSH is suppressed by gonadal production of inhibin, a 31-kd glycoprotein produced by the Sertoli cells. Inhibin consists of a and ß subunits joined by disulfide bonds. The ß-ß dimer (activin) also occurs, but its biologic effect is to stimulate FSH secretion. The biologic features of these newer hormones are being delineated. In addition to its endocrine effect, activin has paracrine effects in the testis. It facilitates LH-induced testosterone production, indicating a direct effect of Sertoli cells on Leydig cells analogous to the interaction of these cells through the paracrine effects of POMC.

The posterior lobe of the pituitary is part of a functional unit, the neurohypophysis, that consists of the neurons of the supraoptic and paraventricular nuclei of the hypothalamus; neuronal axons, which form the pituitary stalk; and neuronal terminals in the median eminence or in the posterior lobe.

Hormones of the Neurohypophysis.

The neurohypophysis is the source of arginine vasopressin (AVP; antidiuretic hormone) and of oxytocin. Both are octapeptides, differing in only two amino acids. These hormones are produced by neurosecretion in the hypothalamic nuclei. Vasopressin derives its name from early observations of its pressor and antidiuretic activities but the latter is its physiologically important function. At levels 50–1,000 times those found in blood, it affects blood pressure, intestinal contractility, hepatic glycogenolysis, platelet aggregation, and release of factor VIII.

Vasopressin and its accompanying protein, called neurophysin II, are encoded by the same gene. A single preprohormone is cleaved and the two are transported to neurosecretory vesicles in the posterior pituitary. The two are released in equimolar amounts. Oxytocin and neurophysin I have a similar relationship.

AVP has a short half-life and responds quickly to changes in hydration. The stimuli for AVP release are increased plasma osmolality, perceived by osmoreceptors in the hypothalamus, and decreased blood volume, perceived by baroreceptors in the carotid sinus of the aortic arch. AVP changes the permeability of the renal tubular cell membrane through cyclic adenosine monophosphate. A synthetic analog, desmopressin combines high potency, selectivity for antidiuretic hormone receptors, and resistance to degradation by proteases. Desmopressin may be given by injection, by intranasal spray, or by mouth. The amount that is required for management of diabetes insipidus depends on the mode of administration. A typical dose is on the order of 1?µg for the injected, 10?µg for the intranasal, and 100?µg for the oral form.

Chapter 551 - Hypopituitarism

John S. Parks

Hypopituitary states are associated with a deficiency of growth hormone (GH), with or without a deficiency of other pituitary hormones (Box 551–1). Affected children have in common a phenotype of postnatal growth impairment that is specifically corrected by replacement of GH.

ISOLATED DEFICIENCY OF GROWTH HORMONE

Genetic Forms.

Isolated GH deficiency (IGHD) can be transmitted as an autosomal recessive (type I), autosomal dominant (type II), or X-linked recessive (type III) trait. IGHD I is caused by mutations of the GH-releasing hormone (GHRH) receptor or the GH1 gene, IGHD II by mutations in the GH1 gene, and IGHD III by mutations in two regions of the X chromosome.

Box 551-1. Etiologic Classification of Hypopituitarism

ISOLATED GROWTH HORMONE DEFICIENCY	
Genetic Forms of GH Deficiency and GH Resistance	
GHRH Receptor	Missense and frameshifts
GH1	
Recessive	Deletions, frameshifts, missense, intron 4 splice errors
Dominant	Intron 3 splice errors
X-Linked	
Xq21.3-q22	May be associated with hypogammaglobulinemia
Xq24-q27.1	May be associated with mental retardation
GH Insensitivity	
GH Receptor	Laron syndrome
IGF-I Gene	Intrauterine and postnatal growth retardation
GH-1 Gene	Arg77Cys, intrauterine and postnatal growth retardation
Acquired GH Deficiency	
Postradiation	Dependent on dose of radiation
Idiopathic	May be transient
MULTIPLE PITUITARY HORMONE DEFICIENCY	
Genetic Forms	
POU1F1	GH, Prl, and TSH deficiencies; normal or small pituitary
PROP1	GH, Prl, TSH, LH, FSH +/- ACTH deficiencies; normal or enlarged pituitary

PROP1	GH, Prl, TSH, LH, FSH +/- ACTH deficiencies; normal or enlarged pituitary
LHX3	GH, Prl, TSH, LH, FSH deficiencies; normal or enlarged pituitary
HESX1	Optic nerve hypoplasia
PTX2-RIEG1	Rieger syndrome with pituitary, eye, GI, and kidney defects
Uncertain Etiology	
Septo-optic dysplasia	
Hall-Pallister syndrome	
Single central incisor	
Holoprosencephaly	
Anencephaly	
Acquired Disorders	
Tumors	Craniopharyngioma, optic glioma, pituitary adenoma
Trauma	Shaken infant, motor vehicle injuries
Inflammatory	Histiocytosis, hypophysitis, tuberculosis
GH = growth hormone; GHRH = growth hormone–releasing hormone; TSH = thyroid-stimulating hormone; ACTH = adrenocorticotropic hormone (corticotropin); LH = luteinizing hormone; FSH = follicle-stimulating hormone; Prl = prolactin.	

Mutations in the GHRH receptor gene occur in several large kindreds from Pakistan, India, and Brazil. Homozygosity for inactivating mutations impairs the proliferation and function of somatotropes. The phenotype consists of modest compromise of fetal growth followed by severe postnatal growth failure. Puberty is delayed, and affected individuals continue to grow into their 20s and 30s. Early recognition and consistent replacement with recombinant GH enables these individuals and others with IGHD to attain normal adult heights.

Mutations and deletions in the GH1 gene produce a similar phenotype. Missense, nonsense, and frameshift mutations are described, but most cases demonstrate mutations in the fourth and final intron of the gene. These mutations eliminate the normal splice donor site used in splicing exon 4 to exon 5. An alternative donor splice site in exon 4 results in a frameshift with production of a messenger RNA encoding a protein that is longer than normal and has no biologic activity.

GH deficiency type I can also be the result of large deletions in the GH gene cluster on chromosome 17q22-24. Deletions of 6.7, 7.0, or 7.6?kb remove only the GH1 gene, whereas deletions of up to 45?kb remove one or more of the adjacent genes termed CSL, CS1, GH2, and CS2 (Chapter 550). The growth phenotype is identical with deletion of GH1 or deletion of GH1 and the other genes. Loss of the other genes without loss of GH1 causes deficiency of chorionic somatomammotropin and placental GH in the maternal circulation, but does not result in fetal or postnatal growth retardation. Homozygosity for GH1 deletion responds initially to GH treatment, but later may develop high titers of GH-binding antibodies and become resistant to GH. The term IGHD IA is applied to these cases; “A” refers to “antibodies” and is used to distinguish it from IGHD IB, which is generally less severe and is not complicated by production of blocking antibodies. This distinction persists in the OMIM classification of GH deficiency even though antibody formation is now the exception rather than the rule in persons with GH1 deletions. The reduction in risk of antibody formation is because preparations of recombinant human GH (hGH) are much less antigenic than the extracted pituitary hGH preparations used previously.

Many cases of autosomal dominant IGHD II have been associated with GH1 mutations. The most common form involves mutation in the splice donor site for intron 3. When this site is altered, exon 3 is omitted from the processed messenger RNA and amino acids 32 to 71 are omitted from the mature protein. Small amounts of the mRNA for this 17,000 molecular weight protein are made in the normal pituitary. When the protein is produced in larger quantities because of an intron 3 mutation, it interferes with production of the normal 22,000 molecular weight protein encoded by the normal allele. This interference probably occurs at the level of transport from microsomes to secretory vesicles. The severity of GH deficiency and growth impairment increases with age. It is not clear whether this progression is associated with reduction in the number of functioning somatotropes.

X-linked recessive IGHD III occurs in the sons of a normal mother and different fathers. In many cases, it is associated with hypogammaglobulinemia. The clinical expression of GH deficiency often follows the expression of immunodeficiency. The hypogammaglobulinemia mapping to Xq21.3-q22 is caused by mutations in the BTK (Bruton thymidine kinase) gene. This gene is expressed in somatotropes as well as in plasma cells. Many persons with mutations in this gene do not experience growth retardation. This may be because only limited spectrums of BTK mutations influence somatotrope function, or persons with the combined defects have disruptions of contiguous genes. In some other pedigrees, X-linked IGHD III maps to a more distal locus, at Xq24-q27.1. In these pedigrees, there is an association of IGHD with mental retardation. It is unclear whether the two features are due to mutations in a

single gene or to disruption of contiguous genes.

Not all cases of heritable IGHD have been linked to the genes mentioned earlier. Although the GHRH gene is a logical candidate, extensive studies have failed to disclose any examples of mutations at this locus in either IGHD I or IGHD II pedigrees.

Acquired Forms.

The GH axis is more susceptible to disruption by acquired conditions than are the other hypothalamic-pituitary axes.

Improved survival of children who receive radiotherapy for malignancies of the central nervous system or other cranial structures has resulted in a group of patients with GH deficiency. Children with acute lymphocytic leukemia who have received prophylactic cranial irradiation belong in this group. Growth typically slows during radiation therapy or chemotherapy, improves for 1–2 yr, then declines with the development of GH deficiency. Spinal irradiation contributes to disproportionately poor growth of the trunk. The dose of radiation and the fractionation schedule used are important determinants of the incidence of hypopituitarism. GH deficiency is almost universal 5 yr after therapy with a total dose of 35–45?Gy. More subtle defects are seen with doses around 20?Gy. Deficiency of GH is the most common defect, but deficiencies of thyroid-stimulating hormone (TSH) and adrenocorticotropic hormone (ACTH) may also occur. In contrast to other forms of hypopituitarism, puberty is not delayed. A pubertal growth spurt at a normal to early age may lessen clinical suspicion of GH deficiency.

Diagnostic strategies for distinguishing between permanent GH deficiency and other causes of impaired growth are imperfect. Children with a combination of genetic short stature and constitutional delay of growth and pubertal development have short stature, below average growth rates, and delayed bone ages. Many of these children exhibit minimal GH secretory responses to provocative stimuli. When children who have been diagnosed with idiopathic or acquired GH deficiency are treated with hGH and are retested as adults, the majority have peak GH levels within the normal range.

PERIPHERAL RESISTANCE TO GROWTH HORMONE

Genetic Forms of Resistance to GH.

There are three recognized mechanisms for end-organ insensitivity to GH. The first, described by Laron, involves abnormalities in the gene on chromosome 5p13-p12 that encodes the receptor for GH. This disease has been recognized in many individuals from many different ethnic backgrounds. Most examples show recessive inheritance, but there are also dominant forms. The second mechanism involves abnormality of the insulin-like growth factor-I (IGF-I) gene and the third involves production of an abnormal GH that serves as a competitive antagonist to the normal hormone.

Children with *Laron syndrome* have all the clinical findings of those with IGHD, but they have elevated levels of circulating GH. Levels of IGF-I are low and fail to respond to exogenous hGH. A variety of gene defects has been discovered in different families, ranging from the deletion of several exons of the gene, through nonsense mutations, to missense mutations, and to mutations that alter splicing of messenger RNA. Most of the mutations produce a loss of GH-binding activity. However, some are associated with normal or increased levels of binding. The mutant protein in at least one family retains normal affinity for GH binding but lacks the ability to form dimers of GH receptor around a single bound GH molecule. In other families, there is increased serum GH binding activity resulting from overproduction of a receptor that lacks the transmembrane domain and has no capacity for signal transduction.

Although mutations in pituitary transcription factor, GHRH receptor, GH, and GH receptor genes have minimal effects on prenatal growth, disruption of the IGF-I gene produces profound intrauterine growth retardation. The single patient described to date was 5.4?SD below the mean for length at birth and 6.9?SD below the mean for height at age 15 yr. He was homozygous for deletion of exons 3 and 4 of the IGF-I gene. There was an absence of circulating IGF-I, but elevated levels of GH and IGF-BP3.

The existence of short stature due to biologically inactive GH was proposed in the 1970s. Some patients with normal to high levels of circulating GH by immunoassay appeared to have lower levels of GH when assessed by receptor binding and cell proliferation assays. The first instance of an antagonistic GH was provided in 1996 in a child who was heterozygous for a mutation changing arginine to cysteine at position 77. The mutant protein binds to GHBP and to the GH receptor, but it does not result in activation of Jak2 kinase. Its dominant negative mechanism of action reflects a higher than normal binding affinity for the receptor. Interestingly, the patient demonstrated severe intrauterine growth retardation similar to that of the child with

abnormalities of the GH1 gene. This suggests that a competitive antagonist for receptor binding has a more severe effect on fetal growth than does complete inactivation of the receptor for GH. One can speculate that inactivation of the prolactin (PRL) receptor as well as the GH receptor is necessary to eliminate endocrine stimuli to fetal production of IGF-I.

MULTIPLE PITUITARY HORMONE DEFICIENCY

Genetic Forms of Multiple Pituitary Hormone Deficiency.

Quite a few genes involved in embryonic development are candidates to explain multiple pituitary hormone deficiency (MPHD) (Chapter 550). There are several distinctive heritable forms of MPHD. Mutations of transcription factor genes that are only expressed in the anterior pituitary lead to simple phenotypes with varying combinations of anterior pituitary hormone deficiencies. Mutations of transcription factor genes that are also expressed in other embryonic tissues give rise to more complex phenotypes that include multiple congenital anomalies.

POU1F1 (PIT1) was originally identified as a nuclear protein that bound to the GH

and PRL promoters. Mutations in POU1F1 are responsible for combined hormone deficiencies in humans. Many different types of recessive loss of function mutations have been identified in humans. Most of the dominant cases have involved a mutation causing substitution of tryptophan for arginine at position 271. The mutant protein has normal to increased promoter-binding activity but is incapable of activating transcription. Persons with POU1F1 mutations exhibit nearly normal fetal growth but experience severe growth failure in the 1st yr of life. There are complete deficiencies of GH and PRL. The severity of TSH deficiency and resultant central hypothyroidism is variable. There is no impairment of ACTH, luteinizing hormone (LH), or follicle-stimulating hormone (FSH) production. Puberty develops spontaneously, though, at a later than normal age.

PROP1 (Prophet of PIT-1) mutations are a very common explanation for the distinctly uncommon phenotype of MPHD. Studies from Switzerland, Poland, and Russia indicate that loss of function mutations are responsible in the majority of cases with a recessive inheritance and about half of the cases with sporadic MPHD. The proportion of sporadic cases that can be explained by PROP1 mutations is even higher when a selection is made for those who have subnormal TSH responses to thyrotropin-releasing hormone (TRH) stimulation. The most common types of mutation involve one or two base pair deletions in the second of three exons. These deletions cause frame shifts and early transcriptional termination, rendering the mutant proteins incapable of binding to promoter sites or activating transcription of target genes. Missense, nonsense, and splice site mutations have also been described. The hormonal phenotypes associated with PROP1 mutations differ in several respects from those associated with POU1F1 mutations. Although the gene defects are present from conception, the hormone deficiencies show the characteristics of an acquired disease. Growth in the 1st yr of life is considerably better than with POU1F1 defects and the median age at diagnosis of GH deficiency is around 6 yr. Recognition of TSH deficiency is delayed relative to recognition of GH deficiency. Basal and TRH-stimulated PRL levels tend to be higher than in POU1F1 mutations. PROP1 mutations cause gonadotropin deficiency and POU1F1 mutations do not. Some patients with PROP1 mutations enter puberty spontaneously and then retreat from it. Girls experience secondary amenorrhea and boys show regression of testicular size and secondary sexual characteristics. There is a loss of LH and FSH responses to luteinizing hormone-releasing hormone (LHRH) stimulation. Partial deficiency of ACTH develops over time in about one third of patients with PROP1 defects. Anterior pituitary size is small in most patients, but in others there is progressive enlargement of the pituitary. A central mass clearly originates within the sella turcica but may extend above it. The cellular content of the mass during the active phase of enlargement is not known. With time, the contents of the mass appear to degenerate, with multiple cystic areas. The mass may persist as a nonenhancing structure or it may disappear completely, leaving an empty sella turcica. At different stages, the findings on MRI can suggest a macroadenoma, a microadenoma, a craniopharyngioma, or a Rathke pouch cyst.

The hormonal phenotype produced by recessive loss of function mutations in the *LHX3 gene* located on chromosome 9q34.3 resembles that produced by PROP1 mutations. There are deficiencies of GH, PRL, TSH, LH, and FSH but not of ACTH. It is not clear whether the deficiencies are present from birth or whether they appear later in childhood. There is another similarity in that some affected individuals show enlargement of the anterior pituitary. The most important distinguishing feature is that each of the cases has had a rigid cervical spine. Imaging does not show any anatomic abnormality, but the patients are only able to rotate their necks about 90 degrees compared with a normal value of 150 to 180 degrees.

Mutations in the *HESX1 gene* also result in a complex phenotype with defects in development of the optic nerve. *Septo-optic dysplasia* or *de Morsier syndrome* is a fairly common condition that combines incomplete development of the septum pellucidum with optic nerve dysplasia. Clinical observation of nystagmus and visual impairment in infancy leads to imaging studies, which, in turn, disclose the optic nerve and brain abnormalities. It is associated with anterior and/or posterior pituitary hormone deficiencies. About 25% of cases have hypopituitarism. These patients tend to show the triad of a small anterior pituitary gland, an attenuated pituitary stalk, and an ectopic posterior pituitary bright spot. The overwhelming majority of cases are sporadic. There seems to be an association with young maternal age but no specific teratogenic agents have been identified. Studies of the HESX1 gene have disclosed abnormalities in three families. Two siblings with hypopituitarism, optic nerve dysplasia, agenesis of the corpus callosum, and a history of parental consanguinity were found to be homozygotes for an inactivating mutation. More mildly affected individuals in two other families were heterozygotes for other inactivating mutations. Homozygotes (in mice) show severe optic nerve and brain abnormalities, whereas some heterozygotes show a milder phenotype.

Rieger syndrome is a complex phenotype caused by mutations in the gene for a transcription factor that is expressed in multiple tissues, including the anterior pituitary gland. In addition to variable degrees of anterior pituitary hormone deficiency, the abnormalities include colobomas of the iris, a high risk of glaucoma, and abnormal development of the kidneys, gastrointestinal tract, and umbilicus. Some cases were found to have deletions or rearrangements of a region on chromosome 4q25. Further studies identified inactivating mutations of the PTX2 (pituitary homeobox 2) gene. Because of its association with Rieger syndrome, it is also known as the *RIEG1* gene. The single normal gene copy in heterozygotes is inadequate to support normal development of a variety of organ systems.

Other Congenital Forms.

Pituitary hypoplasia can occur as an isolated phenomenon or in association with more extensive developmental abnormalities, such as anencephaly or holoprosencephaly (cyclopia, cebocephaly, orbital hypotelorism). Hypoplasia of the pituitary occurs with anencephaly but may have a large residuum of normal pituitary function, suggesting that hypoplasia may be secondary to a hypothalamic defect. Midfacial anomalies (cleft lip, palate) or the finding of a solitary maxillary central incisor indicate a high likelihood of GH or other anterior or posterior hormone deficiency.

In the *Hall-Pallister syndrome*, absence of the pituitary gland is associated with hypothalamic hamartoblastoma, postaxial

polydactyly, nail dysplasia, bifid epiglottis, imperforate anus, and anomalies of the heart, lungs, and kidneys.

Acquired Forms.

Any lesion that damages the hypothalamus, pituitary stalk, or anterior pituitary may cause pituitary hormone deficiency. Because such lesions are not selective, multiple hormonal deficiencies are usually observed. The most common lesion is the craniopharyngioma (Chapter 489). Central nervous system germinoma, eosinophilic granuloma, tuberculosis, sarcoidosis, toxoplasmosis, and aneurysms may also cause hypothalamic-hypophyseal destruction. These lesions are frequently associated with roentgenographic changes in the skull. Besides diabetes insipidus, a deficiency of GH and other pituitary hormones may occur in children with histiocytosis. Enlargement of the sella or deformation or destruction of the clinoid processes usually indicates a tumor. Intrasellar or suprasellar calcifications usually indicate a craniopharyngioma. Trauma, including child abuse, traction at delivery, anoxia, and hemorrhagic infarction, may also damage the pituitary, its stalk, or the hypothalamus. The triad of a small anterior pituitary gland, an attenuated pituitary stalk, and an ectopic posterior pituitary bright spot on MRI has been associated with acquired as well as congenital multiple pituitary hormone deficiency.

CLINICAL MANIFESTATIONS

Congenital Hypopituitarism.

The child with hypopituitarism is usually of normal size and weight at birth. Children with multiple pituitary hormone deficiencies and those with genetic defects of the GH1 or GHR gene have birth length that average 1?SD below the mean. Children with severe defects in GH production or action are more than 4?SD below the mean by 1 yr of age. Others with less severe deficiencies may have regular but slow growth in height, with the increments always less than the normal percentiles; periods of lack of growth may alternate with short spurts of growth. Delayed closure of the epiphyses permits growth beyond the age when normal persons cease to grow. Without treatment, adult heights are 4 to 12?SD below the mean.

Infants with congenital defects of the pituitary or hypothalamus usually present with neonatal emergencies such as apnea, cyanosis, or severe hypoglycemia with or without seizures. Microphallus in boys provides an additional diagnostic clue. Deficiency of GH may be accompanied by hypoadrenalism and hypothyroidism, and clinical manifestations of hypopituitarism evolve more rapidly than in the usual child with hypopituitarism. Prolonged neonatal jaundice is common. It involves elevation of conjugated and unconjugated bilirubin and may be mistaken for neonatal hepatitis.

The head is round, and the face is short and broad. The frontal bone is prominent, and the bridge of the nose is depressed and saddle-shaped. The nose is small, and the nasolabial folds are well developed. The eyes are somewhat bulging. The mandible and the chin are underdeveloped and infantile, and the teeth, which erupt late, are frequently crowded. The neck is short and the larynx is small. The voice is high-pitched and remains high after puberty. The extremities are well proportioned, with small hands and feet. The genitals are usually underdeveloped for the child's age, and sexual maturation may be delayed or absent. Facial, axillary, and pubic hair usually is lacking, and the scalp hair is fine. Length is mainly affected, giving toddlers a pudgy appearance. Symptomatic hypoglycemia, usually after fasting, occurs in 10–15% of children with panhypopituitarism and those with IGHD. Intelligence is usually normal. Affected children may become shy and retiring.

Acquired Hypopituitarism.

The child is normal initially, and manifestations similar to those seen in idiopathic pituitary growth failure gradually appear and progress. When complete or almost complete destruction of the pituitary gland occurs, signs of pituitary insufficiency are present. Atrophy of the adrenal cortex, thyroid, and gonads results in loss of weight, asthenia, sensitivity to cold, mental torpor, and absence of sweating. Sexual maturation fails to take place or regresses if already present. There may be atrophy of the gonads and genital tract with amenorrhea and loss of pubic and axillary hair. There is a tendency to hypoglycemia. Growth slows dramatically. Diabetes insipidus may be present early but tends to improve spontaneously as the anterior pituitary is progressively destroyed.

If the lesion is an expanding tumor, symptoms such as headache, vomiting, visual disturbances, pathologic sleep patterns, decreased school performance, seizures, polyuria, and growth failure may occur. Slowing of growth may antedate neurologic signs and symptoms, especially with craniopharyngiomas, but symptoms of hormonal deficit account for only 10% of presenting complaints. In other patients, the neurologic manifestations may precede the endocrinologic, or evidence of pituitary insufficiency may first appear after surgical intervention. In children with craniopharyngiomas, visual field defects, optic atrophy, papilledema, and cranial nerve palsy are common.

Laboratory Findings.

The diagnosis of classic GH deficiency is suspected in cases of profound postnatal growth failure, with heights more than 3?SD below the mean for age and gender. Acquired GH deficiency can occur at any age. When the disorder is of short duration, height may still be within the normal range. A strong clinical suspicion is important in establishing the diagnosis because laboratory measures of GH sufficiency lack specificity. Observation of low serum levels of IGF-I and the GH-dependent IGF-BP3 can be helpful. Values that are in the upper part of the normal range for age effectively exclude GH deficiency. Values for normally growing and children with hypopituitarism overlap during infancy and childhood.

Definitive diagnosis rests on demonstration of absent or low levels of GH in response to stimulation. A variety of provocative tests have been devised that rapidly increase the level of GH in normal children. These include administration of l-dopa, insulin, arginine, clonidine, or glucagon. Peak levels of GH less than 10?µg/L in each of two provocative tests are compatible with GH deficiency. Stimulation with GHRH or synthetic ghrelin agonists generally produces greater responses in children with GH deficiency secondary to hypothalamic disorders and fails to elicit a response in those with GHRH receptor, GH1, POU1F1, PROP1, and LHX3 mutations. The frequency of false-negative responses to a single standard test in normally growing children is approximately 20%. One study suggests that a majority of normal prepubertal children fail to achieve GH values greater than 10?µg/L with two pharmacologic tests. The researchers suggest that 3 days of estrogen priming should be used

before GH testing to achieve greater diagnostic specificity.

During the 3 decades in which hGH was obtained by extraction from human pituitary glands culled at autopsy, its supply was sharply limited and only patients with classic GH deficiency were treated. With the advent of an unlimited supply of recombinant GH, there has been a marked interest in redefining the criteria for GH deficiency to include children with lesser degrees of deficiency. It has become popular to evaluate the spontaneous secretion of GH by measuring its level every 20?min during a 24- or 12-hr (8 pm–8 am) period. Some short children with normal levels of GH when studied by provocative tests show little spontaneous GH secretion. Such children are considered to have GH neurosecretory dysfunction. With the collection of more normative data, it is clear that frequent GH sampling also lacks diagnostic specificity. There is a wide range of spontaneous GH secretion in normally growing prepubertal children and considerable overlap with the values observed in children with classic GH deficiency. Although the clinical and laboratory criteria for GH deficiency in patients with severe (classic) hypopituitarism

are well established, the diagnostic criteria are unsettled for short children with lesser degrees of GH deficiency.

In addition to establishing the diagnosis of GH deficiency, it is necessary to examine other pituitary functions. Levels of TSH, thyroxine (T_4), ACTH, cortisol, dehydroepiandrosterone sulfate, gonadotropins, and gonadal steroids may provide evidence of other pituitary hormonal deficiencies. The defect can be localized to the hypothalamus if there is a normal response to the administration of hypothalamic-releasing hormones for TSH, ACTH, or gonadotropins. When there is a deficiency of TSH, serum levels of T_4 and TSH are low. A normal increase in TSH and PRL after stimulation with TRH places the defect in the hypothalamus, and absence of such a response localizes the defect to the pituitary. An elevated level of plasma PRL taken at random in the patient with hypopituitarism is also strong evidence that the defect is in the hypothalamus rather than in the pituitary. Some children with craniopharyngioma have elevated PRL levels before surgery, but after surgery, PRL deficiency occurs because of pituitary damage. Antidiuretic hormone deficiency may be established by appropriate studies.

Roentgenographic Examination.

Roentgenograms of the skull are most helpful when there is a destructive or space-occupying lesion causing hypopituitarism. Evidence of increased intracranial pressure may be found in patients with nausea, vomiting, loss of vision, headache, or an increase in circumference of the head. Enlargement of the sella, especially ballooning with erosion and calcifications within or above the sella, may be detected. MRI is indicated in all patients with hypopituitarism. In addition to providing detail about space-occupying lesions, it can define the size of the anterior and posterior pituitary lobes and the pituitary stalk. It is superior to CT in differentiating a full from an empty sella turcica. The posterior pituitary is readily recognized as a bright spot. In many cases of idiopathic MPHD with prenatal or perinatal onset, the posterior pituitary bright spot is ectopic. It appears at the base of the hypothalamus rather than in the pituitary fossa. MRI can provide timely confirmation of suspected hypopituitarism in a newborn with hypoglycemia and micropenis. MRI may also reveal pituitary gland hypoplasia or aplasia, septo-optic dysplasia, holoprosencephaly, or absence of the septum pellucidum.

Skeletal maturation is markedly delayed in patients with long-standing GH deficiency. The bone age tends to be approximately 75% of chronologic age. It may be even more delayed for patients with TSH and GH deficiency. The fontanels may remain open beyond the 2nd yr, and intersutural wormian bones may be found. Long bones are slender and osteopenic. Dual photon x-ray absorptiometry shows deficient bone mineralization, deficiencies in lean body mass, and a corresponding increase in adiposity.

Differential Diagnosis.

The causes of growth disorders are legion. Systemic conditions such as inflammatory bowel disease, celiac disease, occult renal disease, and anemia must be considered. Patients with systemic conditions often have greater loss of weight than length. A few otherwise normal children are short (i.e., >3?SD below the mean for age) and grow 5?cm/yr or less but have normal levels of GH in response to provocative tests and normal spontaneous episodic secretion. Most of these children show increased rates of growth when treated with GH in doses comparable to those used to treat children with hypopituitarism. Plasma levels of IGF-I in these patients may be normal or low. Several groups of treated children have achieved final or near final adult heights. Different studies have found changes in adult height that range from -2.5 to +7.5?cm compared with pretreatment predictions. There are no methods that can reliably predict which of these children will become taller as adults as a result of GH treatment and which will have compromised adult height. Such treatment of short children without proven hypopituitarism is still undergoing experimental trials.

Constitutional growth delay is one of the variants of normal growth commonly encountered by the pediatrician. Length and weight measurements of affected children are normal at birth, and growth is normal for the first 4–12 mo of life. Growth then decelerates to near or below the 3rd percentile for height and weight. By 2–3 yr of age, growth resumes at a normal rate of 5?cm/yr or more. Studies of GH secretion and other studies are within normal limits. Bone age is closer to height age than to chronologic age. Detailed questioning often reveals other family members (frequently one or both parents) with histories of short stature in childhood, delayed puberty, and eventual normal stature. The prognosis for these children to achieve normal adult height is good. Boys with unusual degrees of delayed puberty may benefit from a short course of testosterone therapy to hasten puberty after 14 yr of age. The cause of this variant of normal growth is thought to be persistence of the relatively hypogonadotropic state of childhood (Chapter 14). Constitutional growth delay can be differentiated from genetic short stature by the level of skeletal maturation, which is consistent with chronologic age in the latter condition. Genetic short stature is usually found in other family members. Results of studies of hormones related to growth, however, are normal.

Primary hypothyroidism is usually easily diagnosed on clinical grounds. Responses to GH provocative tests may be subnormal, and enlargement of the sella may be present. Low T_4 and elevated TSH levels clearly establish the diagnosis. Pituitary

hyperplasia recedes during treatment with thyroid hormone. Because thyroid hormone is a necessary prerequisite for normal GH synthesis, its levels must always be assessed before GH studies.

Emotional deprivation is an important cause of retardation of growth and mimics hypopituitarism. The condition is known as psychosocial dwarfism, maternal deprivation dwarfism, or hyperphagic short stature. The mechanisms by which sensory and emotional deprivation interfere with growth are not fully understood. Functional hypopituitarism is indicated by low levels of IGF-I and by inadequate responses of GH to provocative stimuli. Puberty may be normal or even premature in its appearance. Appropriate history and careful observations reveal disturbed mother-child or family relations and provide clues to the diagnosis (Chapter 35.2). Proof may be difficult to establish because the adults responsible often hide the true family situation from professionals, and the children rarely divulge their plight. Emotionally deprived children frequently have perverted or voracious appetites, enuresis, encopresis, insomnia, crying spasms, and sudden tantrums. The subgroup of children with hyperphagia and a normal body mass index tends to show catch-up growth when placed in a less stressful environment.

The *Silver-Russell syndrome* is characterized by short stature, frontal bossing, small triangular facies, sparse subcutaneous tissue, shortened and incurved 5th fingers, and in many cases, asymmetry (i.e., hemihypertrophy). Affected children have low birthweight for gestational age. There is some degree of GH secretory deficiency in very short children with intrauterine growth retardation, whether or not they have Silver-Russell syndrome. Short-term treatment with GH often results in increased rates of growth, particularly when higher than usual doses are used. The impact on adult height of different dosage regimens is still unknown.

Treatment.

The Lawson Wilkins Pediatric Endocrine Society, Academy of Pediatrics, and the GH Research Society have published guidelines for hGH treatment. In children with classic GH deficiency, treatment should be started as soon as possible to narrow the gap in height between patients and their classmates during childhood and to have the greatest effect on mature height. The recommended dose of hGH is 0.18–0.3?mg/kg/wk. It is administered subcutaneously in six or seven divided doses. If the effect of therapy wanes, compliance should be evaluated before the dose is increased. Concurrent treatment with GH and an

LHRH agonist has been used in the hope that interruption of puberty will delay epiphyseal fusion and prolong growth. This strategy may augment final height, but it can also increase the discrepancy in physical maturity between GH-deficient children and their age peers and may impair bone mineralization. Therapy should be continuous until near final height is achieved. Criteria for stopping treatment include a growth rate less than 1 inch per yr and a bone age of greater than 14 yr in girls and greater that 16 yr in boys.

Some patients treated with GH have subsequently acquired leukemia. The risk of leukemia in treated patients may be double that in the general population. There is conflicting evidence about whether GH treatment confers an increase in risk or whether the increased incidence reflects the consequences of therapeutic radiation for craniopharyngiomas and brain tumors. Other reported side effects include pseudotumor cerebri, slipped capital femoral epiphysis, gynecomastia, and worsening of scoliosis. There is an increase in total body water during the first 1–2 wk of treatment. Fasting and postprandial insulin levels are characteristically low before treatment, and they normalize during GH replacement. Development of diabetes mellitus is rare. Older GH-deficient patients treated with cadaver pituitary extracts are at risk for Creutzfeldt-Jakob disease for at least 10–15 yr after therapy. Use of recombinant GH has eliminated this risk.

Maximal response to GH occurs in the 1st yr of treatment. With each successive year of treatment, the response tends to decrease. Some patients receiving GH acquire reversible hypothyroidism. Periodic evaluation of thyroid function is indicated for all patients treated with GH. GHRH is nearly as effective as GH in the treatment of children with hypothalamic causes of hypopituitarism with a deficiency of GHRH, but daily subcutaneous injections are required. Recombinant IGF-I may prove useful in the treatment of children with Laron syndrome and possibly those with GH1 gene deletions and high titers of antibodies.

The doses of GH used to treat children with classic GH deficiency usually enhance the growth of many non–GH-deficient children as well. Intensive investigation is in progress to determine the full spectrum of short children who may benefit from treatment with GH. GH is currently approved in the United States for treatment of children with growth failure as a result of Turner syndrome, end-stage renal failure before kidney transplantation, Prader-Willi syndrome, or intrauterine growth retardation. In children with all other causes of short stature, it is unknown whether GH treatment increases their final height, and treatment of such patients should be confined to prospective clinical trials until further data establish the validity of this expensive, long-term form of therapy.

Replacement should also be directed at other hormonal deficiencies. In TSH-deficient subjects, thyroid hormone is given in full replacement doses. In ACTH-deficient patients, the optimal dose of hydrocortisone should not exceed 10?mg/m^2 /24?hr. Increases are made during illness or in anticipation of surgical procedures. Therapy can often be deferred until growth has been completed if the deficiency is partial. In patients with a deficiency of gonadotropins, gonadal steroids are given when bone age reaches the age at which puberty usually takes place. For infants with microphallus, one or two 3-mo courses of monthly intramuscular injections of 25?mg of testosterone cypionate or testosterone enanthate may bring the penis to normal size without an inordinate effect on osseous maturation.

Chapter 552 - Diabetes Insipidus

David T. Breault
Joseph A. Majzoub

Diabetes insipidus (DI) presents clinically with polyuria and polydipsia and may result from either vasopressin deficiency (central DI) or vasopressin insensitivity at the level of the kidney (nephrogenic DI). Both central DI and nephrogenic DI can arise from inherited defects with congenital or neonatal onset, or be secondary to a variety of causes.

THE PHYSIOLOGY OF WATER BALANCE

The control of extracellular tonicity (osmolality) and volume within a narrow range is critical for normal cellular structure and function. Extracellular fluid tonicity is regulated almost exclusively by water intake and excretion, whereas extracellular volume is regulated by sodium intake and excretion. The control of plasma tonicity and intravascular volume involves a complex integration of endocrine, neural, behavioral, and paracrine systems (Fig. 552–1). Vasopressin, secreted from the posterior pituitary, is the principal regulator of tonicity, with its release largely stimulated by increases in plasma tonicity. Volume homeostasis is largely regulated by the renin-angiotensin-aldosterone system, with contributions from both vasopressin and the natriuretic peptide family.

Vasopressin, a 9-amino acid peptide, has both antidiuretic and vascular pressor activity and is synthesized in the paraventricular and supraoptic nuclei of the hypothalamus. It is transported to the posterior pituitary via axonal projections, where it is stored awaiting release into the systemic circulation. The half-life of vasopressin in the circulation is 5?min. In addition to responding to osmotic stimuli, vasopressin is secreted in response to significant decreases in intravascular volume and pressure (minimum of 8% decrement) via afferent baroreceptor pathways arising from the aortic arch (carotid sinus) and volume receptor pathways in the cardiac

Figure 552-1 Regulation of vasopressin secretion and serum osmolality. Hyperosmolality, hypovolemia, and hypotension are sensed by osmosensors, volume sensors, and barosensors, respectively. These stimulate both vasopressin (VP) secretion and thirst. Vasopressin, acting on the kidney, causes increased reabsorption of water (antidiuresis). Thirst causes increased water ingestion. The results of these dual negative feedback loops cause a reduction in hyperosmolality or hypotension/hypovolemia. Additional stimuli for vasopressin secretion include nausea, hypoglycemia,

and pain. (From Muglia LJ, Majzoub JA: Disorders of the posterior pituitary. In Sperling MA (editor): *Pediatric Endocrinology,* 2nd ed. Philadelphia, WB Saunders, 2002.)

atria and pulmonary veins. Osmotic and hemodynamic stimuli interact synergistically.

The sensation of thirst is regulated by cortical as well as hypothalamic neurons. The thirst threshold is approximately 10?mOsm/kg higher (~293?mOsm/kg) than the osmotic threshold for vasopressin release. Therefore, under conditions of hyperosmolality, vasopressin is released prior to the initiation of thirst, allowing for retention of ingested water. Chemoreceptors present in the oropharynx rapidly downregulate vasopressin release following water ingestion.

Vasopressin exerts its principal effect on the kidney via V2 receptors located primarily in the collecting tubule, the thick ascending limb of the loop of Henle, and the peri-glomerular tubules. The human V2 receptor gene is located on the long arm of the X chromosome (Xq28) at the locus associated with congenital, X-linked, vasopressin-resistant diabetes insipidus. Activation of the V2 receptor results in increases in intracellular cyclic adenosine monophosphate, which leads to the insertion of the aquaporin-2 water channel into the apical (luminal) membrane. This allows water movement along its osmotic gradient into the hypertonic inner medullary interstitium from the tubule lumen and excretion of concentrated urine. In contrast to aquaporin-2, aquaporins-3 and -4 are expressed on the basolateral membrane of the collecting duct cells and aquaporin-1 is expressed in the proximal tubule. These channels may also contribute to urinary concentrating ability.

Atrial natriuretic peptide (ANP), initially isolated from cardiac atrial muscle, has a number of important effects on salt and water balance, including stimulation of natriuresis, inhibition of sodium resorption, and inhibition of vasopressin secretion. ANP is expressed in endothelial cells and vascular smooth muscle where it appears to regulate relaxation of arterial smooth muscle. ANP is also expressed in brain, along with other natriuretic family members; the physiologic role of these factors has yet to be defined.

APPROACH TO THE PATIENT WITH POLYURIA, POLYDIPSIA, AND HYPERNATREMIA

The cause of pathologic polyuria or polydipsia (exceeding 2?L/ m^2 /24?hr) may be difficult to establish in children. Infants may present with irritability, failure to thrive, and intermittent fever. Patients with suspected DI should have a careful history, which should quantify the child's daily fluid intake and output and establish the voiding pattern, e.g., nocturia, or primary or secondary enuresis. A complete physical examination should establish the patient's hydration status and search for any evidence of visual and central nervous system dysfunction as well as other pituitary hormone deficiencies.

If pathologic polyuria or polydipsia is present, the following should be obtained: serum for osmolality, sodium, potassium, blood urea nitrogen, creatinine, glucose, and calcium; urine for osmolality, specific gravity, and glucose determination. The diagnosis of DI is established if the serum osmolality is greater than 300?mOsm/kg and the urine osmolality is less than 300?mOsm/kg. DI is unlikely if the serum osmolality is less than 270?mOsm/kg or the urine osmolality is greater than 600?mOsm/kg. If the patient's serum osmolality is less than 300?mOsm/kg (but greater than 270?mOsm/kg) and pathologic polyuria and polydipsia are present, a water deprivation test is indicated to establish the diagnosis of DI and to differentiate central from nephrogenic causes.

In the inpatient, postneurosurgical setting, central DI is likely if hyperosmolality (serum osmolality > 300?mOsm/kg) is associated with urine osmolality less than serum osmolality. It is important to distinguish between the polyuria resulting from postsurgical central DI and the polyuria resulting from the normal diuresis of fluids received intraoperatively. Both cases may be associated with a large volume (>200?mL/m^2 /h) of dilute urine, although in patients with DI, the serum osmolality is high in comparison to patients undergoing a postoperative diuresis.

552.1 Causes of Hypernatremia (See Chapter 45.2)

CENTRAL DIABETES INSIPIDUS

Central diabetes insipidus can result from multiple etiologies, including genetic mutations in the vasopressin gene; trauma (accidental or surgical) to vasopressin neurons; congenital malformations of the hypothalamus or pituitary; neoplasms; infiltrative, autoimmune, and infectious diseases affecting vasopressin neurons or fiber tracts; and increased metabolism of vasopressin. In approximately 10% of children with central DI, the etiology is idiopathic. Other pituitary hormone deficiencies may be present (Chapter 551).

Box 552.1-1. Differential Diagnosis of Polyuria and Polydipsia

DIABETES INSIPIDUS (DI)

- Central DI
  - Genetic (autosomal dominant)
  - Acquired
    - Trauma (surgical or accidental)
    - Congenital malformations
    - Neoplasms
    - Infiltrative, autoimmune, and infectious diseases
    - Drugs
- Nephrogenic DI
  - Genetic (X-linked, autosomal recessive, autosomal dominant)
  - Acquired
    - Hypercalcemia, hypokalemia
    - Drugs
    - Kidney disease

PRIMARY POLYDIPSIA

DIABETES MELLITUS

Autosomal dominant central DI usually presents within the first 5 yr of life and results from mutations in the vasopressin gene. A number of mutations can cause gene processing defects in a subset of vasopressin expressing neurons. *Wolfram syndrome*, which includes DI, diabetes mellitus, optic atrophy, and deafness, also results in vasopressin deficiency. The gene for this disorder is identified but its function is unknown. Congenital brain abnormalities such as septo-optic dysplasia with agenesis of the corpus callosum, the Kabuki syndrome, holoprosencephaly, and familial pituitary hypoplasia with absent stalk may be associated with central DI and defects in thirst perception. Empty sella syndrome, possibly due to unrecognized pituitary infarction, can be associated with DI in children.

Trauma (to the base of the brain) and neurosurgical intervention (in the region of the hypothalamus or pituitary) are common causes of central DI. The triphasic response following surgery refers to an initial phase of transient DI, lasting 12–48?hr, followed by a second phase of syndrome of inappropriate antidiuretic hormone secretion, lasting up to 10 days, which may be followed by permanent DI. The initial phase may be the result of local edema interfering with normal vasopressin secretion, the second phase results from unregulated vasopressin release from dying neurons, whereas in the third phase, permanent DI results if more than 90% of the neurons have been destroyed.

Given the anatomic distribution of vasopressin neurons over a large area within the hypothalamus, tumors that cause DI must either be very large and infiltrative or be strategically located near the base of the hypothalamus where vasopressin axons converge before their entry into the posterior pituitary. Germinomas and pinealomas typically arise in this region and are among the most common primary brain tumors associated with DI. Germinomas can be very small and undetectable by MRI for several years following the onset of polyuria. For this reason, quantitative measurement of the ß subunit of human chorionic gonadotropin, often secreted by germinomas and pinealomas, should be performed in children with idiopathic or unexplained DI in addition to serial MRI scans. Craniopharyngiomas and optic gliomas can also cause central DI when very large, although this is more often a postoperative complication of the treatment for these tumors. Hematologic malignancies, as with acute myelocytic leukemia, can cause DI via infiltration of the pituitary stalk and sella.

Langerhans cell histiocytosis and lymphocytic hypophysitis are common types of infiltrative disorders causing central DI, with hypophysitis as the cause in 50% of “idiopathic” central DI. Infections involving the base of the brain, including meningitis (meningococcal, cryptococcal, listerial, and toxoplasma), congenital cytomegalovirus infection, and nonspecific inflammatory disease of the brain may give rise to central DI that is often transient. Drugs associated with the inhibition of vasopressin release include ethanol, phenytoin, opiate antagonists, halothane, and a-adrenergic agents.

NEPHROGENIC DIABETES INSIPIDUS

Nephrogenic (vasopressin-insensitive) DI (NDI) can result from genetic or acquired causes. Genetic causes are less common but more severe than acquired forms of NDI. The polyuria and polydipsia associated with genetic NDI usually presents within the first several weeks of life, but may only become apparent after weaning or with longer periods of nighttime sleep. Many infants initially present with fever, vomiting, and dehydration. Failure to thrive may be secondary to the ingestion of large amounts of water resulting in calorie malnutrition. Long-standing ingestion and excretion of large volumes of water may lead to nonobstructive hydronephrosis, hydroureter, and megabladder.

Congenital X-linked NDI results from inactivating mutations of the vasopressin V2 receptor. Congenital autosomal recessive NDI results from defects in the aquaporin-2 gene. An autosomal dominant form of nephrogenic DI is associated with

processing mutations of the aquaporin-2 gene.

Acquired nephrogenic DI may result from hypercalcemia or hypokalemia and is associated with the following drugs: lithium, demeclocycline, foscarnet, clozapine, amphotericin, methicillin, and rifampin. Impaired renal concentrating ability can also be seen with ureteral obstruction, chronic renal failure, polycystic kidney disease, medullary cystic disease, Sjögren syndrome, and sickle cell disease. Decreased protein or sodium intake or excessive water intake, as in primary polydipsia, can lead to diminished tonicity of the renal medullary interstitium and nephrogenic DI.

TREATMENT OF CENTRAL DIABETES INSIPIDUS

Fluid Therapy

With an intact thirst mechanism and free access to oral fluids, a person with complete DI can maintain plasma osmolality and sodium in the high normal range, although at great inconvenience. Neonates and young infants are often best treated solely with fluid therapy, given their requirement for large volumes (3?L/m^2 /24?hr) of nutritive fluid. The use of vasopressin analogs in patients with obligate high fluid intake is contraindicated given the risk of life-threatening hyponatremia.

Vasopressin Analogs

Treatment of central DI in older children is best accomplished with the use of the long-acting vasopressin analog dDAVP (desmopressin). dDAVP is available in an intranasal preparation (onset 5–10?min) and as tablets (onset 15–30?min). The intranasal preparation of dDAVP (10?µg/0.1?mL) can be administered by rhinal tube (allowing dose titration) or by nasal spray. The appropriate dose is determined empirically based on the desired length of antidiuresis. The nasal spray delivers 10?µg (0.1?mL) per spray and is the standard preparation used for treatment of primary enuresis in older children. Use of dDAVP in the treatment of enuresis is a temporizing measure, because it does not affect the underlying condition and should be used with caution. To prevent water intoxication, patients should have at least 1?hr of urinary breakthrough between doses each day. dDAVP tablets are available, but require at least a 10-fold increase in the dose compared with the intranasal preparation. Oral doses of 25–300?µg every 8–12?hr are safe and effective in children.

Aqueous Vasopressin

Central DI of acute onset following neurosurgery is best managed with continuous administration of synthetic aqueous vasopressin (pitressin). Under most circumstances, total fluid intake must be limited to 1?L/m^2 /24?hr during antidiuresis. A typical dose for intravenous vasopressin therapy is 1.5?mU/kg/h, which results in a blood vasopressin concentration of approximately 10?pg/mL. On occasion, following hypothalamic (but not transsphenoidal) surgery, higher initial concentrations of vasopressin may be required to treat acute DI, which has been attributed to the release of a vasopressin inhibitory substance. Vasopressin concentrations greater than 1,000?pg/mL should be avoided because they may cause cutaneous necrosis, rhabdomyolysis, and cardiac rhythm disturbances. Postneurosurgical patients treated with vasopressin infusion should be switched from intravenous to oral fluids as soon as possible to allow thirst sensation, if intact, to help regulate osmolality.

TREATMENT OF NEPHROGENIC DIABETES INSIPIDUS

The treatment of acquired NDI focuses on elimination, if possible, of the underlying disorder, such as offending drugs, hypercalcemia, hypokalemia, or ureteral obstruction. Congenital nephrogenic diabetes insipidus is often difficult to treat. The main goals are to ensure the intake of adequate calories for growth and to avoid severe dehydration. Foods with the highest ratio of caloric content to osmotic load (Na < 1?mmol/kg/24?hr) should be ingested to maximize growth and to minimize the urine volume required to excrete the solute load. Even with the early institution of therapy, however, growth failure and mental retardation are common.

Pharmacologic approaches to the treatment of NDI include the use of thiazide diuretics and are intended to decrease the overall urine output. Thiazides appear to induce a state of mild volume depletion by enhancing sodium excretion at the expense of water and by causing a decrease in the glomerular filtration rate, which results in proximal tubular sodium and water reabsorption. Indomethacin and amiloride may be used in combination with thiazides to further reduce polyuria. High-dose dDAVP therapy, in combination with indomethacin, has been used in some subjects with NDI. This treatment may prove useful in patients with genetic defects in the V2 receptor associated with a reduced binding affinity for vasopressin.

Chapter 553 - Other Abnormalities of Arginine Vasopressin Metabolism and Action

David T. Breault
Joseph A. Majzoub

Hyponatremia (serum sodium < 130?mEq/L) in children is usually associated with severe systemic disorders and is most often due to (1) intravascular volume depletion, (2) excessive salt loss, or (3) hypotonic fluid overload, especially in infants. The syndrome of inappropriate antidiuretic hormone (SIADH) is an uncommon cause of hyponatremia in children, except following vasopressin administration.

The initial approach to the patient with hyponatremia begins with the determination of the volume status. A careful review of the patient's history, physical examination, including changes in weight, and vital signs helps determine whether the patient is hypovolemic or hypervolemic. Supportive evidence includes laboratory data such as serum electrolytes, blood urea nitrogen, creatinine, uric acid, urine sodium, specific gravity, and osmolality (Chapter 45.2) (Tables 553–1 and 553–2).

CAUSES OF HYPONATREMIA

Syndrome of Inappropriate Antidiuretic Hormone Secretion

SIADH is characterized by hyponatremia, an inappropriately concentrated urine (>100?mOsm/kg), normal or slightly elevated plasma volume, a normal-to-high urine sodium, and low serum uric acid. SIADH is uncommon in children, with most cases resulting from excessive administration of vasopressin in the treatment of central diabetes insipidus. It can also occur with encephalitis, brain tumors, head trauma, psychiatric disease, in the postictal period after generalized seizures, after prolonged nausea, pneumonia, tuberculous meningitis, or AIDS. SIADH is the cause of the hyponatremic second phase of the triphasic response seen after hypothalamic-pituitary surgery

TABLE 553-1 -- Differential Diagnosis of Hyponatremia

Disorder	Intravascular Volume Status	Urine Sodium
Systemic dehydration	Low	Low
Decreased effective plasma volume	Low	Low
Primary salt loss	Low	Low
Cerebral salt wasting	Low	Very high
SIADH	High	High
Decreased free water clearance	Normal or high	Normal or high
Primary polydipsia	Normal or high	Normal
Pseudohyponatremia	Normal	Normal
Factitious hyponatremia	Normal	Normal

s

SIADH = syndrome of inappropriate antidiuretic hormone secretion.

(Chapter 552). It is found in up to 35% of patients 1 wk after surgery and may result from retrograde neuronal degeneration with cell death and vasopressin release. Common drugs that have been shown to increase vasopressin secretion or mimic vasopressin action, resulting in hyponatremia, include carbamazepine, chlorpropamide, vinblastine, vincristine, and tricyclic antidepressants.

Systemic Dehydration

The initial manifestation of systemic dehydration is often hypernatremia and hyperosmolality, which subsequently lead to the activation of vasopressin secretion and a decrease in water excretion. As dehydration progresses, hypovolemia and/or hypotension become major stimuli for vasopressin release, further decreasing free water clearance. Urinary sodium excretion is low (usually <10?mEq/L) due to a low glomerular filtration rate and concomitant activation of the renin-angiotensin-aldosterone system, unless primary renal disease or diuretic therapy is present.

Primary Salt Loss

Hyponatremia can result from the primary loss of sodium chloride as seen in specific disorders of the kidney (congenital polycystic kidney disease acute interstitial

nephritis, chronic renal failure), gastrointestinal tract, (gastroenteritis), or sweat glands (cystic fibrosis). The hyponatremia is not solely due to the salt loss, because the latter also causes hypovolemia, leading to an increase in vasopressin. Mineralocorticoid deficiency, pseudohypoaldosteronism (sometimes seen in children with urinary tract obstruction or infection), and diuretics can also result in loss of sodium chloride.

Decreased Effective Plasma Volume

Hyponatremia can result from decreased effective plasma volume, as found in congestive heart failure, cirrhosis, nephrotic

TABLE 553-2 -- Clinical Parameters to Distinguish Between SIADH, Cerebral Salt Wasting and Central Diabetes Insipidus

Clinical Parameter	SIADH	Cerebral Salt Wasting	Central DI
Serum sodium	Low	Low	High
Urine output	Normal or low	High	High
Urine sodium	High	Very high	Low
Intravascular volume status	Normal or high	Low	Low
Serum Uric acid	Low	Normal or high	High
Vasopressin level	High	Low	Low

syndrome, positive pressure mechanical ventilation, severe burns, bronchopulmonary dysplasia in neonates, cystic fibrosis with obstruction, and severe asthma. The resulting decrease in cardiac output leads to reduced water and salt excretion, as with systemic dehydration, and an increase in vasopressin secretion. In patients with impaired cardiac output and elevated atrial volume (e.g., congestive heart failure or lung disease), atrial natriuretic peptide concentrations are elevated further, leading to hyponatremia by promoting natriuresis. These patients usually have a very low urinary excretion of sodium. Unlike dehydrated patients, these patients may have excess total body sodium, from activation of the renin-angiotensin-aldosterone system, and demonstrate peripheral edema as well.

Primary Polydipsia (Increased Water Ingestion)

In patients with normal renal function, the kidney can excrete a dilute urine with an osmolality as low as 50?mOsm/kg. To excrete a daily solute load of 500?mOsm/m^2, the kidney must produce 10?L/m^2 of urine per day. Therefore, to avoid hyponatremia, the maximum amount of water an individual with normal renal function can consume is 10?L/m^2. Neonates, however, cannot dilute their urine to this degree, putting them at risk for water intoxication if water intake exceeds 4?L/m^2 /day (approximately 60?mL/h in a newborn). Many infants develop hyponatremic seizures after being fed pure water without electrolytes rather than breast milk or formula.

Decreased Free Water Clearance

Hyponatremia due to decreased renal free water clearance, even in the absence of an increase in vasopressin secretion, can result from adrenal insufficiency or thyroid deficiency, or be related to a direct effect of drugs on the kidney. Both mineralocorticoids and glucocorticoids are required for normal free water clearance in a vasopressin-independent manner. In patients with unexplained hyponatremia, adrenal and thyroid insufficiency should be considered. Also, patients with coexisting adrenal failure and diabetes insipidus may have no symptoms of the latter until glucocorticoid therapy unmasks the need for vasopressin replacement. Certain drugs may inhibit renal water excretion through direct effects on the nephron, thus causing hyponatremia; these drugs include high-dose cyclophosphamide, vinblastine, cis-platinum, and carbamazepine.

Cerebral Salt Wasting

Cerebral salt wasting appears to be the result of hypersecretion of atrial natriuretic peptide and is seen primarily with central nervous system disorders including brain tumors, head trauma, hydrocephalus, neurosurgery, cerebral vascular accidents, and brain death. Hyponatremia is accompanied by elevated urinary sodium excretion (often more than 150?mEq/L), excessive urine output, hypovolemia, normal or high uric acid, suppressed vasopressin, and elevated atrial natriuretic peptide concentrations (>20?pmol/L). Thus, it is distinguished from SIADH, in which normal or decreased urine output, euvolemia, low uric acid, only modestly elevated urine sodium concentration, and an elevated vasopressin level occur. The distinction between cerebral salt wasting and SIADH is important because the treatment of the two disorders differs markedly.

Pseudohyponatremia and Other Causes of Hyponatremia

Pseudohyponatremia may result from hypertriglyceridemia. In this condition, elevated lipid levels result in a relative decrease in serum water content. As electrolytes are dissolved in the aqueous phase of the serum, they appear low when expressed as a fraction of the total serum volume. As a fraction of serum water, however,

---

electrolyte content is normal. Factitious hyponatremia can result from obtaining a blood sample proximal to the site of intravenous hypotonic fluid infusion.

Hyponatremia is also associated with hyperglycemia, which causes the influx of water into the intravascular space. Serum sodium decreases by 1.6?mEq/L for every

100?mg/dL increment in blood glucose greater than 100?mg/dL. Glucose is not ordinarily an osmotically active agent and does not stimulate vasopressin release, probably because it is able to equilibrate freely across plasma membranes. In the presence of insulin deficiency and hyperglycemia, however, glucose acts as an osmotic agent, presumably because its normal intracellular access to osmosensor sites is prevented. Under these circumstances, an osmotic gradient exists, stimulating vasopressin release.

TREATMENT OF HYPONATREMIA

Patients with systemic dehydration and hypovolemia should be rehydrated with salt-containing fluids such as normal saline or lactated Ringer solution. Because of activation of the renin- angiotensin-aldosterone system, the administered sodium is avidly conserved and a water diuresis quickly ensues as volume is restored and vasopressin concentrations decrease. Under these conditions, caution must be taken to prevent too rapid a correction of hyponatremia, which may result in central pontine myelinolysis characterized by discrete regions of axonal demyelination and the potential for irreversible brain damage.

Hyponatremia due to a decrease in effective plasma volume caused by cardiac, hepatic, renal, or pulmonary dysfunction is more difficult to reverse. The most effective therapy is the least easily achieved: treatment of the underlying systemic disorder. For example, patients weaned from positive pressure ventilation undergo a prompt water diuresis and resolution of hyponatremia as cardiac output is restored and vasopressin concentrations decrease.

Patients with hyponatremia due to primary salt loss require supplementation with sodium chloride and fluids. Initially, intravenous replacement of urine volume with fluid containing sodium chloride, 150 to 450?mEq/L depending on the degree of salt loss, may be necessary; oral salt supplementation may be required subsequently. This treatment contrasts with that of SIADH, in which water restriction without sodium supplementation is the mainstay.

Emergency Treatment of Hyponatremia

The development of acute hyponatremia (onset < 12?hr) or a serum sodium concentration less than 120?mEq/L may be associated with lethargy, psychosis, coma, or generalized seizures, especially in younger children. Acute hyponatremia can cause cell swelling and lead to neuronal dysfunction or to cerebral herniation. The emergency treatment of cerebral dysfunction resulting from acute hyponatremia includes water restriction and may require rapid correction with hypertonic 3% sodium chloride. If hypertonic saline treatment is undertaken, the serum sodium should be raised only high enough to cause an improvement in mental status, and in no case faster than 0.5?mEq/L/hr or 12?mEq/L/24?hr.

Treatment of SIADH

Chronic SIADH is best treated by oral fluid restriction. With full antidiuresis (urine osmolality of 1,000?mOsm/kg), a normal daily obligate renal solute load of 500?mOsmoles/m^2 would be excreted in 500?mL/m^2 water. This, plus a daily nonrenal water loss of 500?mL/m^2 , would require that oral fluid intake be limited to 1,000?mL/m^2 /24?hr to avoid hyponatremia. In young children, this degree of fluid restriction may not provide adequate calories for growth (as discussed). In this situation, the creation of nephrogenic diabetes insipidus using demeclocycline therapy may be indicated to allow sufficient fluid intake for normal growth.

Treatment of Cerebral Salt Wasting

Treatment of patients with cerebral salt wasting consists of restoring intravascular volume with sodium chloride and water, as with the treatment of other causes of systemic dehydration. The underlying cause of the disorder, which is usually due to acute brain injury, should also be treated if possible. Treatment involves the ongoing replacement of urine sodium losses (volume for volume).

Chapter 554 - Hyperpituitarism, Tall Stature, and Overgrowth Syndromes

Pinchas Cohen

HYPERPITUITARISM

Primary hyperpituitarism is a rare event in children, but secondary hypersecretion of pituitary hormones is an expected finding in conditions in which deficiency of a target organ gives decreased hormonal feedback, as in primary hypogonadism or hypoadrenalism. In primary hypothyroidism, pituitary hyperfunction and hyperplasia can enlarge and erode the sella and, on rare occasions, increase intracranial pressure. Such changes should not be confused with primary pituitary tumors; they disappear when the underlying thyroid condition is treated. Pituitary hyperplasia also occurs in response to stimulation by ectopic production of releasing hormones such as that seen occasionally in patients with Cushing syndrome, secondary to corticotropin-releasing hormone excess, or in children with acromegaly secondary to growth hormone-releasing hormone (GHRH) produced by a variety of systemic tumors.

Primary hypersecretion of pituitary hormones by a suspected or proven adenoma is uncommon in childhood. The most commonly encountered pituitary tumors are those that secrete corticotropin, prolactin, or growth hormone (GH). With rare exceptions, pituitary adenomas that secrete gonadotropins or thyrotropin occur in adults. Hypothalamic hamartomas that secrete gonadotropin-releasing hormone are known to cause precocious puberty. It is suspected that some pituitary tumors may result from stimulation with hypothalamic-releasing hormones and in other instances, as in McCune-Albright syndrome (MAS), the tumor is caused by constitutive activating mutation of the G-protein Gs_a gene.

TALL STATURE

The normal distribution of height predicts that 2.5% of the population will be taller than 2?SD (97.5%) above the mean. However, the social acceptability and even desirability of tallness (heightism) make tall stature an uncommon complaint. Nevertheless, it is critical to be able to identify situations in which tall stature or an accelerated growth rate provides a clue to an underlying disorder. In North America, it is extremely unusual for male patients to seek help regarding excessive

height, although in Europe it is somewhat more common. Even in female patients, tall stature has become more socially acceptable, although tall girls may still approach their physician with a desire to curb their growth rate.

Differential Diagnosis of Tall Stature

Box 554–1 lists the causes of tall stature in childhood and adolescence. Of these, the normal variant familial or constitutional tall stature is by far the most common cause. Almost invariably, a family history of tallness can be elicited and no organic pathology is present. The child is often tall throughout childhood and enjoys excellent health. The parent of the constitutionally tall adolescent may reflect unhappily upon his or her own adolescence as a tall teenager. There are no abnormalities in the physical examination and the laboratory studies, if obtained, are negative.

Klinefelter syndrome (XXY syndrome) is a relatively common (1:500–1,000 live male births) abnormality associated with tall stature, mild mental retardation, gynecomastia, and decreased upper to lower body segment ratio. The testes are invariably small, although androgen production by Leydig cells is often at the low normal range. Spermatogenesis and Sertoli cell function are defective and infertility results. Similarly, excess X chromosome material containing an additional dose of the SHOX gene, whose deficiency causes short stature in Turner syndrome, can also cause tall stature. XYY syndrome is associated with tall stature and possible behavioral and mental problems. It is thought that a gene on the Y chromosome (yet to be identified) is responsible for the excess height. Marfan syndrome is an autosomal dominant connective tissue disorder consisting of tall stature, increased arm span, and decreased upper to lower body segment ratio. Additional abnormalities include arachnodactyly,

Box 554-1. Differential Diagnosis of Tall Stature and Overgrowth Syndromes

FETAL OVERGROWTH

- Maternal diabetes mellitus
- Cerebral gigantism (Sotos syndrome)
- Weaver syndrome
- Beckwith-Wiedemann syndrome
- Other IGF-II excess syndromes

POSTNATAL OVERGROWTH LEADING TO CHILDHOOD TALL STATURE

- Familial (constitutional) tall stature
- Cerebral gigantism
- Beckwith-Wiedemann syndrome
- Exogenous obesity
- Excess GH secretion (pituitary gigantism)
- McCune-Albright syndrome or MEN associated with excess GH secretion
- Precocious puberty
- Marfan syndrome
- Klinefelter syndrome (XXY)
- SHOX excess syndromes
- Weaver syndrome
- Fragile X syndrome
- Homocystinuria
- XYY
- Fragile X syndrome
- Homocystinuria
- XYY
- Hyperthyroidism

POSTNATAL OVERGROWTH LEADING TO ADULT TALL STATURE

- Familial (constitutional) tall stature
- Androgen or estrogen deficiency / estrogen resistance (in males)
- Testicular feminization
- ACTH/cortisol deficiency/resistance
- Excess GH secretion (pituitary gigantism)
- Marfan syndrome
- Klinefelter syndrome (XXY)
- XYY

IGF = insulin-like growth factor; ACTH = adrenocorticotropic hormone; GH = growth hormone.

ocular abnormalities, and cardiac anomalies. Homocystinuria is an autosomal recessive inborn error of amino acid metabolism causing mental retardation when untreated, and has many features resembling Marfan syndrome, particularly ocular manifestations. Hyperthyroidism in adolescents is associated with rapid growth but normal adult height. It is almost always caused by Graves disease and is much more common in girls. Children with precocious puberty are often unusually tall but do not develop into giants, because their epiphyses close early and growth ceases prematurely. Rare cases of adrenocorticotropic hormone deficiency or resistance have been associated with tall stature. Exogenous obesity is a common condition in adolescence and may be associated with rapid linear growth and early maturation; adult height is typically normal.

The purpose of the diagnostic evaluation of tall stature is to distinguish the commonly occurring normal variant constitutional variety from the rare pathologic conditions. Often, when the history is suggestive of familial tall stature and the physical examination is entirely normal, no laboratory tests are indicated. It is valuable to obtain a bone age radiograph to predict adult height, which serves as a basis for discussions with the family and for management decisions. If, however, the history is suggestive for any of the aforementioned disorders or the physical examination

reveals abnormalities, additional laboratory tests should be obtained. Insulin-like growth factor-I (IGF-I) and IGF binding protein-3 (IGFBP-3) are excellent screening tests for GH excess and can be verified with a glucose suppression test. Laboratory evidence of GH excess mandates MRI evaluation of the pituitary. Chromosome analysis is useful in boys, especially when the upper to lower body segment ratio is decreased or when mental retardation is present. If Marfan syndrome or homocystinuria is suspected from the physical examination, referral to a cardiologist and an ophthalmologist should be made. Thyroid function tests are useful to diagnose or rule out hyperthyroidism when this disorder is suspected.

PRECOCIOUS AND DELAYED PUBERTY (see chapter 556)

Precocious puberty, whether mediated centrally (increased gonadotropin secretion) or peripherally (increased secretion of androgens, estrogens, or both), results in accelerated linear growth in childhood, mimicking the pubertal growth spurt. Because skeletal maturation is also accelerated, adult height is frequently compromised. The diagnostic evaluation and management of precocious puberty are discussed elsewhere in this book.

Although delayed puberty may be associated with short stature in childhood, as with constitutional delay, failure to eventually enter puberty and complete sexual maturation may result in sustained growth during adult life, with ultimate tall stature. The report of tall stature with open epiphyses resulting from a mutation of the estrogen receptor in a man with normal male sexual maturation underscores the fundamental role of estrogen in promoting epiphyseal fusion and termination of normal skeletal growth. Aromatase deficiency leads to tall stature through similar pathways. Furthermore, androgen insensitivity is associated with tall stature in girls, demonstrating a role for androgens in this process.

MANAGEMENT OF CONSTITUTIONAL AND SYNDROMIC TALL STATURE

Reassurance of the family and the patients is the key to the management of normal variant tall stature. The use of the bone age and a careful assessment of pubertal status to predict adult height may provide some comfort for them, as will general supportive discussions on the social acceptability of this condition. Even though treatment is available for girls and boys with excessive growth, its use should be restricted to patients with (1) predicted adult height > 3?SD above the mean (78 inches or 198?cm

in male patients, 71 inches or 180?cm in female patients) and (2) evidence of significant psychosocial impairment.

For the family of a child with extreme familial tall stature or another condition such as Marfan syndrome who feel strongly about treatment, a trial of sex steroids is possible. Such therapy is designed to accelerate puberty and epiphyseal fusion, and is therefore of little benefit when given in late puberty; therapy is initiated ideally prepubertally or in early puberty. Oral estrogens in various doses have successfully reduced the predicted height of female patients by an average of 5–10?cm. This is a direct result of the known effects of sex steroids on promoting epiphyseal fusion, and therapy must begin before the bone age has reached 12 yr. Oral ethinyl estradiol at a dose of 0.15–0.5?mg/24?hr until cessation of growth occurs has been used successfully in girls. If necessary, a progestational agent can be added after 1 year of unopposed estrogen. In boys, treatment should begin before the bone age reaches 14 yr; testosterone enanthate is used at a dose of 500?mg IM every 2 wk for 6 mo. Whereas no long-term complications of sex steroid therapy have been clearly documented, short-term side effects are common. These include lipid abnormalities, thromboembolism, cholelithiasis, hypertension, nausea, menstrual irregularities, and acne fulminans. The lack of extensive experience with this form of therapy and the risks involved should be carefully weighed and discussed with the family before embarking on therapy.

The mechanism of estrogen action involves effects on both GH and IGF production. Perhaps more important, however, is the action of estrogen on the epiphysis. Recent studies have demonstrated that it is estrogen that mediates epiphyseal fusion in both girls and boys. In prepubertal girls, adult height is reportedly decreased by as much as 5–6?cm relative to pretreatment predictions. When therapy is initiated after the onset of puberty, the decrement in adult height is not likely to be as large. Therapy in boys with tall stature is even more problematic. For the reasons discussed, estrogen is likely to be most efficacious in accelerating epiphyseal fusion but is obviously undesirable in boys. Androgens also accelerate skeletal maturation, presumably via aromatization to estrogen, but at the price of rapid virilization.

PROLACTINOMA

Prolactin-secreting pituitary adenomas are the most common tumors of the pituitary in adolescents. With the advent of MRI, more of these tumors, particularly microadenomas (<1?cm), are being detected. The most common presenting manifestations are headache, amenorrhea, and galactorrhea. The disorder affects more than twice as many girls as boys; most have undergone normal puberty before becoming symptomatic. Only a few patients have delayed puberty. In some kindreds with type I multiple endocrine neoplasia, prolactinomas are the presenting features during adolescence.

Prolactin levels may be moderately (40–50?ng/mL) or markedly (10,000–15,000?ng/mL) elevated. Most prolactinomas in children have been large (macroadenomas), have caused the sella to enlarge, and, in some cases, have caused visual field defects. Approximately one third of patients with macroadenomas develop hypopituitarism, particularly GH deficiency.

Prolactinomas should not be confused with the hyperprolactinemia and pituitary hyperplasia that may occur in patients with primary hypothyroidism, which is readily treated with thyroid hormone. Moderate elevations (<200?ng/mL) of prolactin are also associated with a variety of medications (mainly psychiatric), with pituitary stalk dysfunction such as may occur with craniopharyngioma, and with other benign conditions. Treatment for most children has been surgical resection by transfrontal or transsphenoidal approach. However, the management of prolactinoma is becoming increasingly conservative. Most patients can be effectively managed by treatment with bromocriptine or long-acting cabergoline. About 80% of adult patients respond with shrinkage of the tumor and marked decreases in serum prolactin levels.

EXCESS GROWTH HORMONE SECRETION AND PITUITARY GIGANTISM

In young persons with open epiphyses, overproduction of GH results in gigantism; in persons with closed epiphyses, the result is acromegaly. Often, some acromegalic features are seen with gigantism, even in children and adolescents. After closure of the epiphyses, the acromegalic features become more prominent.

Pituitary gigantism is rare and its cause is most often a pituitary adenoma, but gigantism has been observed in a 2.5-yr-old boy with a hypothalamic tumor that presumably secreted GHRH. Other tumors, particularly in the pancreas, have produced acromegaly by secretion of large amounts of GHRH with resultant hyperplasia of the somatotrophs. The cardinal clinical feature of gigantism is longitudinal growth acceleration secondary to the GH excess. The usual manifestations consist of coarse facial features, and enlarging hands and feet. In young children, rapid growth of the head may precede linear growth. Some patients have behavioral and visual problems. In most of the recorded cases, the abnormal growth became evident at puberty, but the condition has been established as early as the newborn period in one child and at 21 mo of age in another. Giants may grow to a height of 8?ft or more. Acromegalic features consist chiefly of enlargement of the distal parts of the body, but manifestations of abnormal growth involve all portions. The circumference of the skull increases, the nose becomes broad, and the tongue is often enlarged, with coarsening of the facial features. The mandible grows excessively, and the teeth become separated. Visual field defects and neurologic abnormalities are common; signs of increased intracranial pressure appear later. The fingers and toes grow chiefly in thickness. There may be dorsal kyphosis. Fatigue and lassitude are early symptoms. GH levels are elevated and may occasionally exceed 100?ng/mL. There is typically no suppression of GH levels by the hyperglycemia of a glucose tolerance test. IGF-I and IGFBP-3 levels are consistently elevated in gigantism, whereas other growth factors are not. Gigantism is rare, with only several hundred reported cases to date. The presentation of gigantism is usually dramatic, unlike the insidious onset of acromegaly in adults. The tumor mass itself may cause headaches, visual changes due to optic nerve compression, and hypopituitarism. About half of the patients also have marked hyperprolactinemia as a result of plurihormonal adenomas that secrete GH and prolactin. This is due to the fact that mammosomatotrophs are the most common type of GH-secreting cells involved in childhood gigantism. GH-secreting tumors of the pituitary are typically eosinophilic or chromophobe adenomas. Adenomas may compromise other anterior pituitary function through growth or cystic degeneration. Secretion of gonadotropins, thyrotropin, or corticotropin may be impaired. Delayed sexual maturation or hypogonadism may occur. When GH hypersecretion is accompanied by gonadotropin deficiency, accelerated linear growth may persist for decades. In some cases, the tumor spreads outside the sella, invading the sphenoid bone, optic nerves, and brain. GH-secreting tumors in pediatric patients are more likely to be locally invasive or aggressive than are those in adult patients.

The etiology is uncertain although studies in acromegalics have suggested that many cases result from mutations that generate constitutively activated G proteins with reduced GTPase activity. The resultant increase in intracellular cyclic adenosine monophosphate in the pituitary leads to increased GH secretion. MAS, which can also be caused by mutations resulting in constitutively activated G proteins, may also include the presence of somatotrophic tumors and excess GH secretion.

Approximately 20% of patients with gigantism are those with MAS (commonly

---

consisting of a triad of precocious puberty, café au lait spots, and fibrous dyplasia). GH-secreting tumors have also been reported in multiple endocrine adenomatosis and in association with neurofibromatosis, tuberous sclerosis, and Carney complex.

Activating mutations of the stimulatory Gs_a proteins have been found in the pituitary lesions in MAS and are believed to be responsible for the other glandular adenomas observed in this condition as well. Somatic point mutations of the Gs_a protein have also been identified in somatotrophs of up to 40% of sporadic GH secreting pituitary adenomas.

Diagnosis of Growth Hormone Excess

The gold standard for making the diagnosis of GH excess is a failure to suppress serum GH levels to less than 5?ng/dL after a 1.75?g/kg oral glucose challenge (maximum, 75?g). This test measures the ability of IGF-I to suppress GH secretion because the glucose load results in insulin secretion, leading to suppression of IGFBP-1, which results in an acute increase in free IGF-I levels. The increased free IGF-I suppresses GH secretion within 30–90?min. This test can be abnormal in diabetic patients. Note that a single measurement of GH is inadequate because GH is secreted in a pulsatile manner. Therefore, the use of a random GH measurement can lead to both false-positive and false-negative results. Measurement of serum IGF-I concentration is a sensitive screening test for GH excess. An excellent linear dose-response correlation between serum IGF-I levels and 24-hr mean GH secretion has been demonstrated. An elevated IGF-I level in a patient with appropriate clinical suspicion is almost always indicative of GH excess. Potential confusion may arise when evaluating normal adolescents because significantly higher IGF-I levels occur during puberty than in adulthood. For accurate control comparison, the IGF-I level must be age- and gender-matched. Serum IGFBP-3 levels may also be useful in the diagnosis of GH excess. In patients with confirmed somatotroph adenomas, increased IGFBP-3 levels have been reported to be a sensitive marker of GH elevations and may be elevated despite normal IGF-I levels. If laboratory findings suggest GH excess, the presence of a pituitary adenoma should be confirmed using MRI. In rare cases, a pituitary mass may not be identified. This may be due to an occult pituitary microadenoma or an ectopic tumor. CT is acceptable when MRI is unavailable.

Treatment of Growth Hormone Oversecretion

The goals of therapy are to remove or shrink the pituitary mass, to restore GH and secretory patterns to normal, to restore IGF-I and IGFBP-3 levels to normal, to retain the normal pituitary secretion of other hormones, and to prevent recurrence of disease.

For well-circumscribed pituitary adenomas, transsphenoidal surgery is the treatment of choice and may be curative. The tumor should be removed completely. The

likelihood of surgical cure depends greatly on the surgeon's expertise as well as on the size and extension of the mass. Intraoperative GH measurements can improve the results of tumor resection. Transsphenoidal surgery to resect the tumors has been shown to be as safe in children as in adults. At times, a transcranial approach may be necessary. The primary goal of treatment is to normalize GH levels. GH levels (<1?ng/mL within 2?hr after a glucose load) and serum IGF-I levels (age adjusted normal range) are the best tests to define a biochemical cure.

If GH secretion is not normalized by surgery, the options include pituitary radiation and medical therapy. In general, radiotherapy is recommended if GH hypersecretion is not normalized by surgery. Further growth of the tumor is prevented by radiation in more that 99% of the patients. The main disadvantage is the delayed efficacy in decreasing GH levels. GH is reduced approximately 50% from the initial concentration by 2 yr, 75% by 5 yr, and approaches 90% by 15 yr. Hypopituitarism is a predictable outcome, occurring in 40–50% of patients 10 yr after irradiation.

Surgery fails to cure a significant number of patients and therefore medical therapy has taken on a more important role in the management of patients with GH excess. Treatment has been improved by the availability of effective and well-tolerated long-acting somatostatin analogs and dopamine agonists as well as by novel GH antagonists.

The somatostatin analogs have been found to be highly effective in the treatment of patients with GH excess. Octreotide suppresses GH to less than 2.5?ng/mL in 65% of patients with acromegaly and normalizes IGF-I levels in 70%. Studies of patients for more than 14 yr have shown that the effects of octreotide are well sustained over time. Tumor shrinkage also occurs with octreotide, but it is generally modest. Consistent GH suppression was obtained with a continuous SC pump infusion of octreotide in a pubertal boy with pituitary gigantism. Long- acting formulations, including long-acting octreotide and lanreotide, produce consistent GH and IGF-I suppression in acromegalic patients with once monthly or biweekly IM depot injections. The sustained release preparations have not been formally tested in children. Sandostatin injection in the pediatric population has been used at doses of 1–40 μg/kg/24?hr.

For cases that have both GH and prolactin oversecretion, one should consider dopamine agonists, such as bromocriptine, which bind to pituitary dopamine type 2 (D_2) receptors and suppress GH secretion, although the precise mechanism of action remains unclear. Prolactin levels are often adequately suppressed; however, GH levels and IGF-I levels are rarely normalized with this treatment modality. Less that 20% of patients achieve GH levels less that 5?ng/mL and less than 10% achieve normalization of IGF-I levels. Tumor shrinkage occurs in a minority of patients. It is generally used as adjuvant medical treatment for GH excess. Its effectiveness may be additive to that of octreotide. Long-acting formulations are available; however, data on long-term control of GH and IGF-I with these agents is not yet available. The dose of bromocriptine ranges from 10–60?mg/24?hr PO divided qid. However, only a minority of patients benefit from doses greater than 20?mg/24?hr. It has been found to be safe when used in children for an extended period of time, but side effects may include nausea, vomiting, abdominal pain, arrhythmias, nasal stuffiness, orthostatic hypotension, sleep disturbances, and fatigue.

A novel GH receptor antagonist is approved for use in acromegaly (pegvisomant). It is an analog of human growth hormone that functions as a growth hormone-receptor antagonist. It effectively suppressed GH and IGF-I levels in patients with acromegaly from pituitary tumors as well as ectopic GHRH hypersecretion. Normalization of IGF-I levels occurs in up to 90% of patients treated daily with this drug for 3 mo or longer. Long-term studies need to be performed. It has not been tested in children. The adult dose is 10–30?mg via subcutaneous injection once daily.

SOTOS SYNDROME (CEREBRAL GIGANTISM)

Children with cerebral gigantism (also known as Sotos syndrome) are typically above the 90th percentile for both length and weight at birth and macrocrania may also be noted at that time. Although it is characterized by rapid growth, there is no evidence that Sotos syndrome is an endocrine disorder. A hypothalamic defect has been suggested as a cause, but none has been demonstrated functionally or at necropsy. Growth is rapid, and by 1 yr of age, affected infants are greater than the 97th percentile in height. Accelerated growth continues for the first 4–5 yr and then returns to a normal rate. Puberty usually occurs at the normal time but may occur slightly early. Adult height is usually in the upper normal range. The hands and feet are large,

---

with thickened subcutaneous tissue. The head is large and dolichocephalic, the jaw is prominent, there is hypertelorism, and the eyes have an antimongoloid slant. Clumsiness and awkward gait are characteristic, and affected children have great difficulty in sports, in learning to ride a bicycle, and in other tasks requiring coordination. Some degree of mental retardation affects most patients; in some children, perceptual deficiencies may predominate. Osseous maturation is compatible with the patient's height. GH and IGF-I levels and results of other endocrine studies are usually normal; there are no distinctive laboratory or radiologic markers for the syndrome. Abnormal electroencephalograms are common; imaging studies frequently reveal a dilated ventricular system. Most cases are sporadic. Familial cases are usually consistent with autosomal dominant inheritance and occasionally with autosomal recessive inheritance. Affected patients may be at increased risk for neoplasia, particularly hepatic carcinoma, but Wilms, ovarian, and parotid tumors have been reported. A genetic basis for Sotos syndrome has recently been proposed to involve NSD1, a transcription factor whose function is being unraveled. A typical case is shown in Figure 554–1 .

OVERGROWTH IN THE FETUS

Maternal diabetes constitutes the most common cause of infants who are large for gestational age (LGA). Even in the absence of clinical symptoms or a family history, the birth of an excessively large infant should lead to evaluation for maternal (or gestational) diabetes.

Figure 554-1 Cerebral gigantism in an 8-yr-old boy. The height age was 12 yr; the bone age was 12 yr. IQ was 60. The electroencephalogram had abnormal findings. Notice the prominence of the forehead and the jaw and the large hands and feet. Sexual development was consistent with

chronological age. Hormone study results were normal. The adult height was 208?cm (6?ft 10?in); his sexual development was normal. He wears size 18 shoes.

A group of disorders associated with excessive somatic growth and growth of specific organs, has been described and are collectively referred to as overgrowth syndromes. These disorders appear to be caused by excess availability of IGF-II encoded by the gene Igf2. The best described of these syndromes is the *Beckwith-Wiedemann syndrome (BWS)*, which is an overgrowth malformation syndrome that occurs with an incidence of 1:13,700 births. It is manifest as a fetal overgrowth syndrome in which hypertrophy dominates the clinical picture. Typically macroglossia, omphalocele, hepatosplenomegaly, nephromegaly, and hypoglycemia secondary to pancreatic ß cell hyperplasia in an LGA baby comprise the clinical picture at birth. An additional complication is that these children are predisposed to a specific subset of childhood neoplasms, among which are Wilms tumor and adrenocortical carcinoma. Overexpression of IGF-II in BWS may be caused by a number of genetic disruptions including gene duplication, loss of heterozygosity, and relaxation or loss of imprinting of the Igf2 gene. Various lines of investigation have localized “imprinted” genes involved in BWS and associated childhood tumors to chromosome 11p. These include, in addition to Igf2, the gene H19, which is involved in Igf2 suppression as well as the gene WT-1 (the Wilms tumor gene). Mutations in GPC3, a glypican gene (which code for an IGF-II neutralizing membrane receptor), cause the related *Simpson-Golabi-Behmel overgrowth syndrome*.

Chapter 555 - Physiology of Puberty

Luigi Garibaldi

Between early childhood and approximately 8–9 yr of age (i.e., *prepubertal* stage), the hypothalamic-pituitary-gonadal axis is dormant, as reflected by undetectable serum concentrations of luteinizing hormone (LH) and sex hormones (i.e., estradiol in girls, testosterone in boys). In this phase, the activity of the hypothalamus and pituitary is thought to be suppressed by poorly characterized neuronal restraint pathways.

One to 3 yr before the onset of puberty becomes clinically evident, low serum levels of LH during sleep become demonstrable (i.e., *peripubertal* period). This sleep-entrained LH secretion occurs in a pulsatile fashion and probably reflects endogenous episodic discharge of hypothalamic gonadotropin-releasing hormone (GnRH). Nocturnal pulses of LH continue to increase in amplitude and, to a lesser extent, in frequency as clinical puberty approaches. This pulsatile secretion of gonadotropins is responsible for enlargement and maturation of the gonads and the secretion of sex hormones. The appearance of the secondary sex characteristics in *early puberty* is the visible culmination of the sustained, active interaction occurring among hypothalamus, pituitary, and gonads in the peripubertal period. By *midpuberty*, LH pulses become evident even during the daytime and occur at about 90–120?min intervals.

A second critical event occurs in middle or late adolescence in girls, in whom cyclicity and ovulation occur. A positive feedback mechanism develops whereby increasing levels of estrogen in midcycle cause a distinct increase of LH.

The factors that normally activate or restrain the hypothalamic neurons responsible for GnRH secretion (i.e., neurosecretory unit known as the *GnRH pulse generator*) are unknown. In nonhuman primates, a decline in the ? aminobutyric acid (GABA)-ergic tone in hypothalamic neurons and the resultant increase in the glutamate-ergic tone have been shown to activate the GnRH pulse generator. Several other neurotransmitters are probably involved in humans and other primates.

It is clear that GnRH is the major, if not the only, hormone responsible for the onset and progression of puberty, because pubertal development can be reproduced in sexually immature or gonadotropin-deficient animals and humans by pulsed administration of GnRH.

The interpretation of the hormonal changes of puberty is complex because of several factors. First, pituitary gonadotropins are heterogeneous and circulate in multiple isoforms: more-bioactive isoforms of LH may be preponderant during puberty. Second, LH immunoreactivity is variable in different immunoassays, and the results of LH measurements vary widely among laboratories. Third, the pulsatile secretion of gonadotropins and the synergism of follicle-stimulating hormone and LH in promoting gonadal maturation make interpretation of single serum gonadotropin concentrations difficult. Measurement of gonadotropins in serially obtained (every 10–20?min for 12–24?hr) serum samples or timed urine collections is more meaningful. Fourth, important sex differences exist in the maturation of the hypothalamus and pituitary gland, and serum LH concentrations increase earlier in the course of the pubertal process in boys than in girls.

The effects of gonadal steroids (i.e., testosterone in boys, estradiol in girls) on bone growth and osseous maturation have become increasingly clear in the last decade, with the characterization of estrogen deficiency states in male patients. Both aromatase deficiency and estrogen receptor defects result in delayed epiphyseal fusion and tall stature in affected boys. These observations suggest that estrogens, rather than androgens, are responsible for the process of bone maturation that ultimately leads to epiphyseal fusion and cessation of growth. Estrogens also mediate the increased production of growth hormone, which along with a direct effect of sex steroids on bone growth, is responsible for the pubertal growth spurt.

The age of onset of puberty varies and is more closely correlated with osseous maturation than with chronological age (Chapter 14). In girls, the breast bud is usually the first sign of puberty (10–11 yr), followed by the appearance of pubic hair 6–12 mo later. The interval to menarche is usually 2–2.5 yr but may be as long as 6 yr. In the United States, at least one sign of puberty is present in approximately 95% of girls by 12 yr of age and in 99% of girls by 13 yr of age. Peak height velocity occurs early (at breast stage II–III, typically between 11 and 12 yr of age) in girls and always precedes menarche. The mean age of menarche is about 12.75 yr. There are, however, wide variations in the sequence of changes involving growth spurt, breast bud, pubic hair, and maturation of the internal and external genitalia.

In boys, growth of the testes (>3?mL in volume or 2.5?cm in longest diameter) and thinning of the scrotum are the first signs of puberty. These are followed by pigmentation of the scrotum and growth of the penis (Chapter 14). Pubic hair then appears. Appearance of axillary hair usually occurs in midpuberty. In boys, unlike girls, acceleration of growth begins after puberty is well under way and is maximal at genital stage IV–V (typically between 13 and 14 yr of age). In boys, the growth spurt occurs approximately 2 yr later than in girls, and growth may continue beyond 18 yr of age.

Genetic and environmental factors affect the onset of puberty. Following a decrease in menarcheal age in the past century, probably reflecting better nutrition and improved general health, the age of menarche has been stable for the last 30–40 yr. American black girls may be more advanced in development of secondary sex characteristics than white girls. Ballet dancers, gymnasts, runners, and other female

athletes in whom leanness and strenuous physical activity have coexisted from early childhood frequently exhibit a marked delay in puberty or menarche, and frequently have oligomenorrhea or amenorrhea as adults. This observation supports the thesis that the energy balance is closely related to the activity of the GnRH pulse generator and the mechanisms initiating and sustaining puberty, perhaps via hormonal signals originating from the adipocytes (leptin and others peptides).

Adrenal cortical androgens also play a role in sexual maturation. Serum levels of dehydroepiandrosterone (DHEA) and its sulfate (DHEAS) begin to increase at approximately 6–8 yr of age, before any increase in LH or sex hormones and before the earliest physical changes of puberty are apparent; this process has been called adrenarche. DHEAS is the most abundant adrenal C-19 steroid in the blood, and its serum concentration remains fairly stable over 24?hr. A single measurement of this hormone is commonly used as a marker of adrenal androgen secretion. Although adrenarche typically antedates the onset of gonadal activity (i.e., gonadarche) by a few years, the two processes do not seem to be causally related, because adrenarche and gonadarche are dissociated in conditions such as central precocious puberty and adrenocortical failure.

Chapter 556 - Disorders of Pubertal Development

Luigi Garibaldi

Precocious puberty is generally defined as the onset of secondary sexual characteristics before 8 yr of age in girls and 9 yr in boys. This definition is somewhat arbitrary, however, because of the marked variation in the age at which puberty begins in normal children, particularly in different ethnic groups.

Precocious pubertal development may be classified as gonadotropin dependent, also called *true* or *central* precocious

Box 556-1. Conditions Causing Precocious Puberty

GONADOTROPIN-DEPENDENT PUBERTY (TRUE PRECOCIOUS PUBERTY)

- Idiopathic
- Organic brain lesions
  - Hypothalamic hamartoma
  - Brain tumors, hydrocephalus, severe head trauma, myelomeningocele
- Hypothyroidism, prolonged and untreated

COMBINED GONADOTROPIN-DEPENDENT AND GONADOTROPIN-INDEPENDENT PUBERTY

- Treated congenital adrenal hyperplasia
- McCune-Albright syndrome, late
- Familial male precocious puberty, late

GONADOTROPIN-INDEPENDENT PUBERTY (PRECOCIOUS PSEUDOPUBERTY)

Females

- Isosexual (feminizing) conditions
  - McCune-Albright syndrome
  - Autonomous ovarian cysts
  - Ovarian tumors
  - McCune-Albright syndrome
  - Autonomous ovarian cysts
  - Ovarian tumors
    - Granulosa-theca cell tumor associated with Ollier disease
    - Teratoma, chorionepithelioma
    - Sex-cord tumor with annular tubules (SCTAT) associated with Peutz-Jeghers syndrome
  - Feminizing adrenocortical tumor
  - Exogenous estrogens
- Heterosexual (masculinizing) conditions
  - Congenital adrenal hyperplasia
  - Adrenal tumors
  - Ovarian tumors
  - Glucocorticoid receptor defect
  - Exogenous androgens

Males

- Isosexual (masculinizing) conditions
  - Congenital adrenal hyperplasia
  - Adrenocortical tumor
  - Leydig cell tumor
  - Familial male precocious puberty
    - Isolated
    - Associated with pseudohypoparathyroidism
  - hCG-secreting tumors
    - Central nervous system
    - Hepatoblastoma
    - Mediastinal tumor associated

Central nervous system

Hepatoblastoma

Mediastinal tumor associated with Klinefelter syndrome

Teratoma

Glucocorticoid receptor defect

Exogenous androgen

Heterosexual (feminizing) conditions

Feminizing adrenocortical tumor

SCTAT associated with Peutz-Jeghers syndrome

Exogenous estrogens

INCOMPLETE (PARTIAL) PRECOCIOUS PUBERTY

Premature thelarche

Premature adrenarche

Premature menarche

puberty, or gonadotropin independent, also called *peripheral* precocious puberty or precocious *pseudopuberty* (Box 556–1). True precocious puberty is always isosexual and stems from hypothalamic-pituitary-gonadal activation. The gonadotropin-mediated increase in the size and activity of the gonads leads to increasing sex hormone secretion and progressive sexual maturation. In precocious pseudopuberty, some of the secondary sex characteristics appear, but there is no activation of the normal hypothalamic-pituitary-gonadal interplay. In this latter group, the sex characteristics may be isosexual or heterosexual (“contrasexual”) (see Chapters 576 to 582).

Precocious pseudopuberty may induce maturation of the hypothalamic-pituitary-gonadal axis and eventually trigger the onset of true sexual precocity. This mixed type of precocious puberty occurs commonly in conditions such as congenital adrenal hyperplasia, McCune-Albright syndrome, and familial male-limited precocious puberty, when the bone age reaches the pubertal range (10.5–12.5 yr).

556.1 Gonadotropin-Dependent Precocious Puberty

The condition occurs at least 10-fold more frequently in girls than in boys and is usually sporadic, although some cases are familial. Despite the widespread use of CT scans and MRI, more than 90% of sexual precocity in girls is idiopathic. A structural central nervous system (CNS) abnormality can, however, be demonstrated in 25–75% of boys and in some girls with central precocious puberty. A high prevalence of idiopathic sexual precocity has been reported in girls adopted from developing countries, with the limitations that the exact date of birth may be uncertain in some cases.

Clinical Manifestations.

Sexual development may begin at any age and generally follows the sequence observed in normal puberty. In girls, the first sign is development of the breast; pubic hair may appear simultaneously but more often appears later. Maturation of the external genitalia, the appearance of axillary hair, and the onset of menstruation follow. The early menstrual cycles may be more irregular than they are with normal puberty. The initial cycles are usually anovulatory, but pregnancy has been reported as early as 5.5 yr of age (Fig. 556–1 (Figure Not Available)).

In boys, enlargement of the testes is followed by enlargement of the penis, appearance of pubic hair, and acne. Erections are common, and nocturnal emissions may occur. The voice deepens, and linear growth is accelerated. Testicular biopsies have shown stimulation of all elements of the testes, and spermatogenesis has been observed as early as 5–6 yr of age.

In affected girls and boys, height, weight, and osseous maturation are advanced. The increased rate of bone maturation results in early closure of the epiphyses, and the ultimate stature is less than it would have been otherwise. Without treatment, approximately one third of girls and an even larger percentage of boys achieve a height less than the 5th percentile as adults. Mental development is usually compatible with chronological age. Emotional behavior and mood swings are common, but serious psychological problems are rare.

Although the clinical course is variable, three main patterns of pubertal progression can be identified. Most girls (particularly those younger than 6 yr of age at the onset) and most boys have *rapidly progressive* sexual precocity, characterized by rapid physical and osseous maturation, leading to a loss of height potential. Several girls (generally older than 6 yr of age at the onset) have a *slowly progressive variant*, characterized by parallel advancement of osseous maturation and linear growth, with preserved height potential. A slowly progressive variant of central sexual precocity

Figure 556.1-1 (Figure Not Available) Idiopathic precocious puberty. Patient (*A*) at 311/12, (*B*) at 58/12, and (*C*) at 8½ yr of age. Breast development and vaginal bleeding began at 2½ yr of age. Osseous age was 7½ yr at 311/12 and 14 yr at 8 yr of age. Repeated estrogen assays varied between normal prepubertal and adult female levels. Urinary gonadotropins were not demonstrable until the child was 5 yr of age. Intelligence and dental age were normal for chronological age. Growth was completed at 10 yr; ultimate height was 142?cm (56?in).

has recently been reported in boys, too, but it appears to be much less common than in girls. A small percentage of girls have spontaneously regressive or *unsustained* central precocious puberty. This variability in the natural course of sexual precocity

underscores the need for longitudinal observation at the onset of sexual development, before treatment is considered.

Laboratory Findings.

Sex hormone concentrations are usually appropriate for the stage of puberty in both sexes. Thus, serum estradiol concentrations in girls are low or undetectable in the early phase of sexual precocity, as they are in normal puberty. In boys, serum testosterone levels are detectable or clearly elevated by the time the parents seek medical attention, particularly if an early morning blood sample is obtained.

Sensitive immunometric (including immunoradiometric, immunofluorometric, and chemiluminescent) assays for luteinizing hormone (LH) have largely replaced the traditional LH radioimmunoassays and offer greater diagnostic sensitivity using random blood samples. With these new assays, serum LH concentrations are undetectable in prepubertal children, but they become detectable in 50–70% of girls and a higher percentage of boys with central sexual precocity. Measurement of LH in serial blood samples obtained during sleep has greater diagnostic power than measurement in a single random sample, and it typically reveals a well-defined pulsatile secretion of LH. Intravenous administration of gonadotropin-releasing hormone *(GnRH stimulation test)* or a GnRH agonist (leuprolide stimulation test) is a helpful diagnostic tool, particularly for boys, in whom a brisk LH response (LH peak >5–10 IU/L) with predominance of LH over follicle-stimulating hormone (FSH) occurs in the early phase of precocious puberty. In girls with sexual precocity, however, the nocturnal LH secretion and the LH response to GnRH may be quite low at breast stage II–early stage III (immunometric-LH peak, often <5 IU/L), and the LH:FSH ratio may remain low until midpuberty. In such girls with “low” LH response, the central nature of sexual precocity can be proven by detecting pubertal levels of estradiol (>50 pg/mL), 20–24?hr after stimulation with leuprolide.

Osseous maturation is variably advanced, often more than 2–3 SD. Pelvic ultrasonography in girls reveals progressive enlargement of the ovaries, followed by enlargement of the uterus to pubertal size. A CT or MRI scan usually demonstrates physiologic enlargement of the pituitary gland, as seen in normal puberty, and sometimes reveals CNS pathology (see later text).

Differential Diagnosis.

Organic CNS causes of central sexual precocity should be ruled out by MRI scans, particularly in girls without pubic hair, in girls with estradiol greater than 30?pmol/L, in girls younger than 6 yr of age, and in all boys. However, in children presenting without neurologic signs or symptoms, the CNS lesions causing precocious puberty are rarely malignant and seldom require neurosurgical intervention.

Gonadotropin-independent causes of isosexual precocious puberty must be considered in the differential diagnosis (see Box 556–1). For girls, these include tumors of the ovaries, autonomously functioning ovarian cysts, feminizing adrenal tumors, McCune-Albright syndrome, and exogenous sources of estrogens. For boys, congenital adrenal hyperplasia, adrenal tumors, Leydig cell tumors, chorionic gonadotropin-producing tumors, and familial male precocious puberty should be considered.

Treatment.

The observation that the pituitary gonadotropic cells require pulsatile, rather than continuous, stimulation by GnRH to maintain the ongoing release of gonadotropins provides the rationale for using GnRH agonists for treatment of central precocious puberty. By virtue of being more potent and having a longer duration of action than native GnRH, these GnRH analogs (after a brief period of stimulation) “desensitize” the gonadotropic cells of the pituitary to the stimulatory effect of endogenous GnRH and effectively halt the progression of central sexual precocity. Virtually all boys and the large subgroup of girls with rapidly progressive precocious puberty are candidates for treatment. However, girls with slowly progressive puberty do not seem to benefit in terms of height prognosis from GnRH-agonist therapy. Rare patients require treatment for psychological or social reasons alone.

Depot formulations of long-acting GnRH analogs, which maintain fairly constant serum concentration of the drug for weeks, constitute the preparations of choice for treatment of central precocious puberty. Leuprolide acetate (Lupron Depot Ped), the only depot preparation approved for this use in the United States, is given in a dose of 0.25–0.3?mg/kg (minimum, 7.5?mg) intramuscularly once every 4 wk. Other long-acting preparations (D-Trp6-GnRH [Decapeptyl]; goserelin acetate [Zoladex]) are approved for treatment of precocious puberty in other countries. Recurrent sterile fluid collections at the sites of injections is the most troublesome local side effect and occurs in less than 5% of treated patients. In children with such local reactions, treatment should be changed to subcutaneous injections of aqueous leuprolide, given once or twice daily (total dose 60?µg/kg/24?hr), or intranasal administration of the GnRH agonist nafarelin [Synarel], 800?µg bid. However, the potential for irregular compliance with daily administration, as well as the variable absorption of the intranasal route for nafarelin, may limit the long-term benefit of the latter preparations on adult height. GnRH antagonists have only recently become commercially available and are currently under study for treatment of sexual precocity.

Treatment results in decrease of the growth rate, generally to age-appropriate values, and an even greater decrease of the rate of osseous maturation. Some children, particularly those with greatly advanced (pubertal) bone age, may show marked deceleration of their growth rate and a complete arrest in the rate of osseous maturation. Treatment results in enhancement of the predicted height, although the actual adult height of patients followed to epiphyseal closure is approximately 1 SD less than their midparental height. In girls, breast development may regress in those with Tanner stage II–III development. Most commonly, the size of the breasts remains unchanged in girls with stage III–V development or may even increase slightly because of progressive adipose tissue deposition. The amount of glandular tissue decreases. Pubic hair usually remains stable in girls, or may even progress slowly during treatment, reflecting the gradual increase in adrenal androgens. Menses, if present, cease. Pelvic sonography demonstrates a decrease of the ovarian and uterine size. In boys, there is decrease of testicular size, variable

regression of pubic hair, and decrease in the frequency of erections. Except for a reversible decrease in bone density (of uncertain clinical significance), no serious adverse effects of GnRH analogs have been reported in children treated for sexual precocity.

If treatment is effective, the serum sex hormone concentrations decrease to prepubertal levels (testosterone, <20?ng/dL in boys; estradiol, <10?pg/mL in girls). The serum LH and FSH concentrations, as measured by sensitive immunometric assays, decrease to less than 1?IU/L, although rarely does the LH return to truly prepubertal levels (<0.1 IU/L). Moreover, the incremental FSH and LH responses to GnRH stimulation decrease to less than 1–2 IU/L. Serum LH and sex hormone levels remain suppressed for as long as therapy is continued, but puberty resumes promptly when therapy is discontinued. In girls, menarche and ovulatory cycles generally appear within 6–18 mo of cessation of therapy. The addition of human growth hormone (hGH) to GnRH agonists has been used in children with precocious puberty, markedly advanced bone age, and poor height prediction. Preliminary data suggest that combined therapy may improve the adult height.

556.2 Precocious Puberty Resulting from Organic Brain Lesions

Etiology.

With the advent of CT and especially MRI scans, *hypothalamic hamartoma* has been recognized as one of the most common brain lesions causing true precocious puberty (Fig. 556–2 (Figure Not Available)). This congenital malformation consists of ectopically located

Figure 556.2-2 (Figure Not Available) Precocious puberty with central nervous system lesion. Photographs at 1.5 (*A*) and 2.5 (*B*) yr of age. Accelerated growth, muscular development, osseous maturation, and testicular development were consistent with the degree of secondary sexual maturation. In early infancy, the patient began having frequent spells of rapid, purposeless motion; later in life, he had episodes of uncontrollable laughing with ocular movements. At 7 yr, he exhibited emotional lability, aggressive behavior, and destructive tendencies. Although a hypothalamic hamartoma had been suspected, it was not established until CT scanning became available, when the patient was 23 yr of age. Epiphyses fused at 9 yr of age; final height was 142?cm (56?in). At 24 yr of age, he developed an embryonal cell carcinoma of the retroperitoneum.

neural tissue containing GnRH-secretory neurons and may function as an accessory GnRH pulse generator. On MRI, it appears as a small pedunculated mass attached to the tuber cinereum or the floor of the third ventricle or, less often, as a sessile mass (Fig. 556–3), which remains static in size over years. This lesion is infrequently associated with gelastic or psychomotor seizures.

A wide variety of lesions of the CNS, usually involving the hypothalamus by scarring, invasion, or pressure, have been associated with gonadotropin-dependent sexual precocity. These lesions probably induce sexual maturation by interrupting poorly characterized pubertal restraint pathways. They include postencephalitic scars, tuberculous meningoencephalitis, tuberous sclerosis, severe head trauma, and hydrocephalus, either isolated or associated with myelomeningocele. Neoplasms causing precocious puberty include astrocytomas, ependymomas, and optic tract tumors. Tumors of the latter type (typically slowly progressive or indolent optic gliomas) are highly prevalent (15–20%) in children with neurofibromatosis type 1 (NF-1) and constitute the main etiologic factor for the central sexual precocity encountered in a small subset (approximately 3%) of children with NF-1.

About half of the tumors in the pineal region are germinomas or astrocytomas; the remainder consists of a wide variety of

---

Figure 556.2-3 MRI of a central nervous system lesion in a child with central precocious puberty. A 6-yr-old girl was referred for stage IV breast development and growth acceleration. Serum luteinizing hormone and estradiol concentrations were in the adult range. The midsagittal T1-weighted image shows an isointense hypothalamic mass (*arrowheads*), typical of a hamartoma. (From Sharafuddin M, Luisiri A, Garibaldi LR, et al: MR imaging diagnosis of cerebral precocious puberty: Importance of changes in the shape and size of the pituitary gland. *Am J Roentgenol* 1994;162:1167.)

histologically distinct tumor types. These tumors, too, cause precocious puberty by interrupting CNS inhibitory pathways to the hypothalamus or, in boys only, by secreting human chorionic gonadotropin (hCG), which stimulates the Leydig cells of the testes. Intracranial hCG-secreting germinomas usually do not produce precocious puberty in girls, presumably because complete ovarian function cannot occur without FSH priming.

Clinical Manifestations.

Some of these tumors or malformations (e.g., hypothalamic hamartomas) remain static in size or grow slowly, producing no signs other than precocious puberty. For lesions causing neurologic symptoms, the neuroendocrine manifestations may be present for 1–2 yr before the tumor can be detected radiologically. Hypothalamic signs or symptoms such as diabetes insipidus, adipsia, hyperthermia, unnatural crying or laughing (gelastic seizures), obesity, and cachexia should suggest the possibility of an intracranial lesion. Visual signs (e.g., proptosis) may be the first manifestation of an optic glioma.

The sexual precocity is always isosexual, and the endocrine patterns are generally those found in children without demonstrable organic lesions. Rapidly progressive sexual precocity in very young children suggests the likelihood of a hypothalamic hamartoma. In conditions other than hypothalamic hamartoma, growth hormone deficiency may occur and may be masked by the growth-promoting effect of the increased sex hormone levels.

Treatment.

Neurosurgical intervention is not indicated for hypothalamic hamartomas, except in rare patients with intractable seizures. For other neurologic lesions, therapy depends on the nature and location of the pathologic process. Regardless of the cause, therapy with GnRH analogs is as effective in children with organic brain lesions causing central precocious puberty as it is in children with idiopathic sexual precocity, and the analogs are the therapy of choice to halt premature sexual development. Combined growth hormone therapy should be considered for patients

with associated growth hormone deficiency.

556.3 Precocious Puberty Following Irradiation of the Brain

Radiation therapy, generally for leukemia or intracranial tumors, increases the risk of precocious puberty considerably, whether the irradiation is directed to the hypothalamic area or to areas of the brain anatomically distant from the hypothalamus. Low-dose radiation (18–24 Gy) hastens the onset of puberty almost exclusively in girls. High-dose radiation (25–47 Gy), conversely, appears to trigger precocious sexual development in both sexes, and the risk of sexual precocity is inversely proportional to the age of the child at the time radiation was given.

This type of sexual precocity often occurs in the face of growth hormone deficiency, and may be associated with other conditions (e.g., spinal radiation, hypothyroidism) adversely affecting the prognosis for a reasonable adult height. Unless careful attention is paid to early signs of pubertal development in these children, the combination of growth hormone deficiency and the growth promoting effect of sex steroids often results in a “normal” growth rate at the expense of a rapidly advancing bone age and impaired adult height potential.

Treatment.

As in other types of central precocious puberty, GnRH analogs are very effective in arresting pubertal progression in this patient population. However, concomitant growth hormone deficiency (and/or thyroid hormone deficiency) need to be diagnosed and treated promptly in order for the adult height prognosis to improve.

Paradoxically, hypopituitarism with gonadotropin deficiency may subsequently develop as a late effect of high-dose CNS radiation in patients with or without a history of precocious puberty, and may require substitution therapy with sex steroids.

556.4 Syndrome of Precocious Puberty and Hypothyroidism

In children with untreated hypothyroidism, the onset of puberty is usually delayed until epiphyseal maturation has reached 12–13 yr of age. Precocious puberty in a child with untreated hypothyroidism and a prepubertal bone age presents a strikingly unphysiologic association, yet is not uncommon and may occur in as many as 50% of children with severe hypothyroidism of long duration. These children have the usual manifestations of hypothyroidism, including retardation of growth and of osseous maturation. The cause of the hypothyroidism is often undiagnosed lymphocytic thyroiditis and rarely thyroidectomy or overtreatment with antithyroid drugs.

Sexual development in girls consists primarily of breast enlargement and menstrual bleeding; the latter may occur even in girls with minimal breast enlargement. Pelvic sonography may reveal large, multicystic ovaries. Boys have testicular enlargement associated with modest or no penile enlargement and no pubic hair development. Enlargement of the sella, which is typical of long-standing primary hypothyroidism, may be demonstrated by skull film or MRI. Plasma levels of thyroid-stimulating hormone (TSH) are markedly elevated, often greater than 500?µU/mL, and those of prolactin are mildly elevated.

Although serum FSH is low and LH is undetectable, when measured by specific assays, the massively elevated concentrations of TSH appear to interact with the FSH receptor (“specificity spillover”), thus inducing FSH-like effects in the absence of LH effects on the gonads. As a consequence, unlike in true precocious puberty, testicular enlargement occurs without substantial Leydig cell stimulation and testosterone secretion in affected boys. In affected girls, ovarian estrogen production occurs without a concomitant increase in androgens. Thus, the precocious puberty associated with hypothyroidism behaves as an incomplete form of gonadotropin-dependent puberty. Treatment of the hypothyroidism results in rapid return to normal of the biochemical and clinical manifestations. Macroorchidism (testicular volume > 30?mL) may persist in adult life despite adequate thyroxine therapy.

556.5 Gonadotropin-Secreting Tumors

Hepatic Tumors.

Isosexual precocious puberty may be uncommonly associated with hepatoblastoma. All reported cases have been male, with the age of onset varying from 4?mo–8 yr (average, 2 yr). An enlarged liver or mass in the upper quadrant should suggest the diagnosis. The tumor cells produce hCG, which stimulates the LH receptors in the Leydig cells of the testes. The testicular histology reveals interstitial cell hyperplasia and absence of spermatogenesis. Plasma levels of hCG and a-fetoprotein are usually markedly elevated; they serve as useful markers for following the effects of therapy. Plasma levels of testosterone are elevated, and the FSH and LH levels, as measured by specific, immunometric assays, are low; in the past, LH levels were falsely elevated because of cross-reaction with hCG on radioimmunoassay.

Treatment for these tumors is the same as that for other carcinomas of the liver; prognosis for survival beyond 1–2 yr from the time of diagnosis is poor.

Other Tumors.

Chorionic gonadotropin-secreting choriocarcinomas, teratocarcinomas, or teratomas (also called ectopic pinealomas or atypical teratomas), located in the CNS, mediastinum, gonads, or even adrenal glands, may cause precocious puberty, more commonly (10- to 20-fold) in boys than in girls. Affected patients often have marked elevations of hCG and a-fetoprotein. Mediastinal tumors, but not gonadal tumors, have been reported to cause precocious puberty in boys with Klinefelter syndrome.

Precocious Pseudopuberty.

The adrenal causes of pseudopuberty are discussed in Chapter 570 , and the gonadal causes are discussed in Chapters 578 and 581 .

556.6 McCune-Albright Syndrome (Precocious Puberty with Polyostotic Fibrous Dysplasia and Abnormal Pigmentation)

This is a syndrome of endocrine dysfunction associated with patchy cutaneous pigmentation and fibrous dysplasia of the skeletal system. Although sexual precocity in girls was the major recognized endocrinopathy in the past, associated pituitary, thyroid, and adrenal aberrations are also recognized. The disorder is characterized by autonomous hyperfunction of many glands and is caused by a missense mutation in the gene encoding the a-subunit of G_S , the G protein that stimulates cyclic adenosine monophosphate (cAMP) formation, resulting in the formation of the putative *gsp* oncoprotein. Activation of receptors (e.g., corticotropin [ACTH], TSH, FSH, LH receptors) that operate with a cAMP-dependent mechanism, as well as cell proliferation, ensue. Because the mutation is somatic, rather than genomic, it is expressed differently in different glands or tissues; hence, the variability of clinical expression in different patients.

Precocious puberty has been described predominantly in girls (Fig. 556–4 (Figure Not Available)). The average age at onset in affected girls is about 3 yr, but vaginal bleeding has occurred as early as 4 mo of age and secondary sex characteristics have occurred as early as 6 mo. Young girls have suppressed levels of LH and FSH, and there is no response to GnRH stimulation. Estradiol levels vary from normal to markedly elevated (>900?pg/mL), are often cyclic, and may correlate with the size of the cysts. In boys, precocious puberty is less common but has been reported in several instances. Unlike ovarian enlargement in girls, testicular enlargement in boys is fairly symmetric. It is followed by the appearance of phallic enlargement and pubic hair, as in normal puberty. Testicular histology has demonstrated large seminiferous tubules and no or minimal Leydig cell hyperplasia; these findings may simply reflect the fact that biopsy specimens were obtained at an early stage of pubertal development. In girls and boys, when the bone age reaches the usual pubertal age range, gonadotropin secretion begins, and the response to GnRH becomes pubertal. True (gonadotropin-dependent) precocious puberty overrides the antecedent (gonadotropin-independent) precocious pseudopuberty. In girls, menses become more regular, but often not completely, and fertility has been documented.

Pubertal progression is variable in these patients. Functioning ovarian cysts often disappear spontaneously; aspiration or surgical excision of cysts is rarely indicated. For girls with persistent estradiol secretion, agents that interfere with the final step of estrogen biosynthesis, that is, aromatase inhibitors such as testolactone, letrozole or anastrozole, or antiestrogens (such as tamoxifen) may limit, to a variable extent, the estrogen effects on pubertal and osseous maturation. These compounds, however, have not been approved by the Food and Drug Administration for this indication; tamoxifen may be hepatotoxic. Associated therapy with long-acting analogs of GnRH is indicated only for patients whose puberty has shifted from a gonadotropin-independent to a predominantly gonadotropin-dependent mechanism.

Extragonadal Manifestations.

The hyperthyroidism that occurs in this condition differs from that characteristic of Graves disease. There is an equal distribution among male and female patients; the goiters are multinodular. Clinical hyperthyroidism is uncommon in children, but goiters, mildly elevated triiodothyronine levels, suppressed TSH levels, and abnormalities on ultrasound have been reported. Only rarely is thyroidectomy necessary.

In patients with associated Cushing syndrome, bilateral nodular adrenocortical hyperplasia has occurred in early infancy, antedating the sexual precocity. ACTH levels are low, and adrenal function is not suppressed by large doses of dexamethasone. Treatment is bilateral adrenalectomy.

Increased secretion of growth hormone occurs uncommonly and is manifested clinically by gigantism or acromegaly or by increased rates of growth even in the absence of precocious puberty. Girls and boys are equally affected. Serum levels of growth hormone are elevated and increase during sleep; they are augmented by thyrotropin (TRH) and poorly inhibited by oral glucose. Serum levels of prolactin are increased in most patients, but fewer than half of the patients have a demonstrable pituitary tumor. Octreotide, a long-acting somatostatin analog, has been used to treat the hypersomatotropism. The prognosis is favorable for longevity, but deformities, repeated fractures, pain, and occasional cranial nerve compression may result from the bony lesions.

Of the extraglandular manifestations, phosphaturia, leading to rickets or osteomalacia, is the most common. Cardiovascular

---

Figure 556.6-4 (Figure Not Available) Precocious puberty associated with polyostotic fibrous dysplasia (McCune-Albright syndrome) in a girl 4.5 yr of age; at this time, her height age and osseous age were normal. Menarche occurred at 4 yr of age. *A*, Notice the bilateral breast development, the hyperpigmented spots on the abdomen, and the prominence of the left side of the face. *B*, Roentgenograms revealed fibrous dysplasia in the distal end of the left ulna and thickening of the bones about the left orbit and the maxillary portion of the frontal bones shown here.

and hepatic involvement is rare but may be life-threatening (e.g., severe neonatal cholestasis).

556.7 Familial Male Gonadotropin-Independent Precocious Puberty

This is a rare, autosomal dominant form of sexual precocity that is transmitted from affected males and unaffected female carriers of the gene to their male offspring. Signs of puberty appear by 2–3 yr of age. The testes are only slightly enlarged. Testicular biopsies show Leydig cell maturation and, in some instances, marked hyperplasia. Maturation of seminiferous tubules may be present. Testosterone levels are markedly elevated to the same range seen in boys with true precocious puberty; however, baseline levels of LH are prepubertal, pulsatile secretion of LH is absent, and LH does not respond to stimulation with GnRH. The cause for activation of Leydig cells independent of gonadotropin stimulation is a missense mutation of the LH receptor leading to constitutive activation of cAMP production.

Osseous maturation may be markedly advanced; when it reaches the pubertal age range, hypothalamic maturation shifts the mechanism of pubertal development to a

gonadotropin-dependent one. This sequence of events is similar to that occurring in children with McCune-Albright syndrome (see earlier discussion) or in those with congenital adrenal hyperplasia (see Chapter 570.1).

Gonadotropin-independent precocious puberty has been diagnosed in a few unrelated boys with type IA pseudohypoparathyroidism who had a single mutation of the G_s a protein. This mutation is inactivating at normal body temperature and causes pseudohypoparathyroidism, but in the cooler temperature of the testes, it is constitutionally activating, resulting in adenyl cyclase stimulation and production of testosterone. Although this mutation differs from the constitutive LH receptor (mutation), which usually causes familial male gonadotropin-independent precocious puberty, the end result is the same.

Treatment.

Young boys have been successfully treated with ketoconazole (600?mg/24?hr in 8-hr divided doses), an antifungal drug that inhibits C-17,20-lyase and testosterone synthesis. Other investigators have used a combination of spironolactone (to block androgen action) and aromatase inhibitors (such as testolactone, letrozole, or anastrozole), because estrogens derived from androgens stimulate bone maturation. These medications are unable to revert the serum testosterone to the normal (prepubertal) concentrations or completely offset the unfavorable effects of the elevated sex hormones. They slow down, but do not halt, the progression of puberty and may not improve the height prognosis. Boys whose GnRH pulse generator has matured require combined therapy with GnRH agonists.

556.8 Incomplete (Partial) Precocious Development

Isolated manifestations of precocity without development of other signs of puberty are not unusual; development of the breasts in girls and growth of sexual hair in both sexes are the two most common forms.

Premature Thelarche.

This term applies to a transient condition of isolated breast development that most often appears in the first 2 yr of life; in some girls breast development is present at birth and persists. Breast development may be unilateral or asymmetric and often fluctuates in degree. Growth and osseous maturation are normal or slightly advanced. The genitalia show no evidence of estrogenic stimulation. The condition is usually sporadic and is rarely familial. Breast development may regress after 2 yr, often persists for 3–5 yr, and is rarely progressive. Menarche occurs at the expected age, and reproduction is normal. Basal serum levels of FSH and the FSH response to GnRH stimulation may be greater than that seen in normal controls. Plasma levels of LH and estradiol are consistently less than the limits of detection. Ultrasound examination of the ovaries reveals normal size, but a few small (<9?mm) cysts are not uncommon.

In some girls of the same age group, breast development may be associated with definite evidence of systemic estrogen effects, such as growth acceleration or bone age advancement. Pelvic sonography may reveal enlarged ovaries or uterus. This condition has been referred to as *exaggerated* or *atypical thelarche*. It differs from central sexual precocity because it has spontaneous regression. GnRH stimulation elicits a robust FSH response and a minimal LH response. The pathogeneses of typical and exaggerated forms of thelarche are unclear, although a delay in the transition from the activated (neonatal-infantile) to the inactive (prepubertal) pituitary-ovarian axis may underlie both conditions.

Premature thelarche is a benign condition but may be the first sign of true or pseudoprecocious puberty, or it may be caused by exogenous exposure to estrogens. In addition to a detailed history, a bone age should be obtained. The serum concentrations of FSH, LH, and estradiol are generally low and not diagnostic. Pelvic ultrasound examination is rarely indicated. Continued observation is important because the condition cannot be readily distinguished from true precocious puberty. Regression and recurrence suggest functioning follicular cysts. Occurrence of thelarche in children older than 3 yr of age most often is caused by a condition other than benign precocious thelarche.

Premature Pubarche (Adrenarche).

This term applies to the appearance of sexual hair before the age of 8 yr in girls or 9 yr in boys without other evidence of maturation. It is much more frequent in girls than in boys and may occur more frequently in American black girls than in others. Hair appears on the mons and labia majora in girls, perineal and scrotal area in boys; axillary hair generally appears later. Adult-type axillary odor is common. Affected children are slightly advanced in height and osseous maturation.

Premature adrenarche is an early maturational event of adrenal androgen production. This event coincides with precocious maturation of the zona reticularis, an associated decrease in 3ß-hydroxysteroid-dehydrogenase activity, and an increase in C-17,20-lyase activity. These enzymatic changes result in increased basal and ACTH-stimulated serum concentrations of the $?^5$ -steroids (17-hydroxypregnenolone and DHEA) and, to a lesser extent, of the $?^4$ -steroids (particularly androstenedione) compared with age-matched control subjects. The levels of these steroids and those of DHEAS are usually comparable to those of children in the early stages of normal puberty.

Premature adrenarche is a benign condition that requires no therapy. However, a subset of patients with precocious pubarche has one or more features of systemic androgen effect, such as marked growth acceleration, clitoral (girls) or phallic (boys) enlargement, cystic acne, or advanced bone age (>2 SD above the mean for age). In these patients with *atypical premature adrenarche*, an ACTH stimulation test with measurement of steroid intermediates (mainly serum 17-hydroxyprogesterone concentrations) is indicated to rule out nonclassic congenital adrenal hyperplasia due to 21-hydroxylase deficiency. Epidemiologic and molecular-genetic studies have shown that the prevalence of nonclassical 21-hydroxylase deficiency is approximately 3–6% of unselected children presenting with precocious pubarche; the prevalence of other enzyme defects (i.e., 3ß-hydroxysteroid-dehydrogenase or

11ß-hydroxylase deficiencies) is extremely low.

Although idiopathic premature adrenarche has been considered a benign condition, longitudinal observations suggest that approximately 50% of girls with premature adrenarche are at high risk for hyperandrogenism and polycystic ovarian syndrome, alone or, more often, in combination with other components of the so-called metabolic syndrome (insulin resistance possibly progressing to type 2 diabetes mellitus; dyslipidemia; hypertension; increased abdominal fat) as adults. An increased risk of premature adrenarche and the metabolic syndrome has been documented in children born small for their gestational age. This appears to be associated with insulin resistance and decreased beta-cell reserve, perhaps as a consequence of fetal undernutrition.

Premature Menarche.

This is a very rare entity, much less frequent than premature thelarche or premature adrenarche, and is a diagnosis of exclusion. In girls presenting with isolated vaginal bleeding in the absence of other secondary sexual characteristics, more common causes such as vulvovaginitis, foreign body, or sexual abuse, and uncommon causes such as urethral prolapse and sarcoma botryoides must be carefully excluded. The majority of girls with idiopathic premature menarche have only 1–3 episodes of bleeding; puberty occurs at the usual time and menstrual cycles are normal. Plasma levels of gonadotropins are normal, but estradiol levels may be elevated, probably owing to bursts of ovarian activity. Occasional patients are found to have ovarian follicular cysts on ultrasound.

556.9 Medicational Precocity

A variety of medicaments can induce the appearance of secondary sexual characteristics that may be confused with precocious puberty. A careful history focused on exploring the possibility of accidental exposure to or ingestion of sex hormones is important. Precocious pseudopuberty has occurred in both boys and girls from the accidental ingestion of estrogens (including contraceptive pills) and from the administration of anabolic steroids. Estrogens in cosmetics, hair creams, and breast augmentation creams have caused breast development in girls and gynecomastia in boys; estrogens are readily absorbed through the skin. The high prevalence of premature thelarche and precocious pseudopuberty in Puerto Rico for the last 2 decades has been attributed to contamination of meats, particularly chicken, with estrogens used in animal husbandry but has not been proved. Exogenous estrogens may produce an intense, dark brown color in the areola of the breasts that is not usually seen in endogenous types of precocity. The precocious changes disappear after cessation of exposure to the hormones. Recently, the widespread use of testosterone gel, which is applied to the skin for treatment of male hypogonadism, has resulted in virilization of children and women following skin contact at, and systemic absorption from, the area where the gel was applied.

Section 2 - *Disorders of the Thyroid Gland*

Stephen LaFranchi

Chapter 557 - Thyroid Development and Physiology

FETAL DEVELOPMENT

The fetal thyroid bilobed shape is recognized by 7 wk of gestation, and characteristic thyroid follicle cell and colloid formation is seen by 10 wk. Thyroglobulin synthesis occurs from 4 wk, iodine trapping by 8–10 wk, and thyroxine (T_4) and, to a lesser extent, triiodothyronine (T_3) synthesis and secretion occur from 12 wk of gestation. There is evidence that three transcription factors, TTF-1, TTF-2, and PAX8, are important in thyroid gland morphogenesis and differentiation. These factors also bind to the promotors of thyroglobulin and thyroid peroxidase genes and so influence thyroid hormone production. Hypothalamic neurons synthesize thyrotropin-releasing hormone (TRH) by 6–8 wk, the pituitary portal vessel system begins development by 8–10 wk, and thyroid-stimulating hormone (TSH) secretion is seen by 12 wk of gestation. Maturation of the hypothalamic-pituitary-thyroid axis occurs over the second half of gestation, but normal feedback relationships are not mature until approximately 3 mo of postnatal life. Another transcription factor, Pit-1, is important for differentiation and growth of thyrotrophs, along with somatotrophs and lactotrophs.

THYROID PHYSIOLOGY

The main function of the thyroid gland is to synthesize T_4 and T_3 . The only known physiologic role of iodine is in the synthesis of these hormones; the recommended dietary allowance of iodine is greater than 30?µg/kg/24?hr for infants, 70–120?µg/24?hr for children, and 150?µg/24?hr for adolescents and adults. The daily intake in North America varies from 240 to more than 700?µg. The median iodine intake in the United States has decreased by approximately 50% between the 1970s and the 1990s. Whatever the chemical form ingested, iodine eventually reaches the thyroid gland as iodide. Thyroid tissue has an avidity for iodine and is able to trap (with a gradient of 100:1), transport, and concentrate it in the follicular lumen for synthesis of thyroid hormone. Iodine transport is carried out by the

sodium-iodide symporter, the gene for which has been cloned.

Before trapped iodide can react with tyrosine, it must be oxidized; this reaction is catalyzed by thyroidal peroxidase. The thyroid cells also elaborate a specific thyroprotein, a globulin with approximately 120 tyrosine units (thyroglobulin). Iodination of tyrosine forms monoiodotyrosine and diiodotyrosine; two molecules of diiodotyrosine then couple to form one molecule of T_4 or one molecule of diiodotyrosine and one of monoiodotyrosine to form T_3 . Once formed, hormones are stored as thyroglobulin in the lumen of the follicle (colloid) until ready to be delivered to the body cells. Thyroglobulin is a large globular glycoprotein with a molecular weight of about 660,000 and under normal conditions is detectable in the blood of most individuals at nanogram levels. T_4 and T_3 are liberated from thyroglobulin by activation of proteases and peptidases.

The metabolic potency of T_3 is three to four times that of T_4 . In adults, the thyroid produces approximately 100?µg of T_4 and 20?µg of T_3 daily. Only 20% of circulating T_3 is secreted by the thyroid; the remainder is produced by deiodination of T_4 in the liver, kidney, and other peripheral tissues by type I 5'-deiodinase. Selenocysteine is the active center of the iodothyronine deiodinases. Thus, selenium indirectly plays a role in normal growth and development. In the pituitary and brain, approximately 80% of required T_3 is produced locally from T_4 by a different enzyme, type II 5'-deiodinase. In the fetal rat, although plasma levels of T_3 are very low, cerebral concentrations increase to almost adult levels. The level of T_3 in blood is 1/50th that of $T_{4,}$ but T_3 is the physiologically active thyroid hormone.

The thyroid hormones increase oxygen consumption, stimulate protein synthesis, influence growth and differentiation, and affect carbohydrate, lipid, and vitamin metabolism. The free hormones enter cells, where T_4 may be converted to T_3 by deiodination. Intracellular T_3 then enters the nucleus, where it binds to thyroid hormone receptors. Thyroid hormone receptors are members of the steroid hormone receptor superfamily that includes glucocorticoids, estrogen, progesterone, vitamin D, and retinoids. Four different isoforms of the thyroid hormone receptor ($a_{1,}$ a_2 , $ß_1$, and $ß_2$) are expressed in different tissues; the protein product of the formerly designated *c-erb A* proto-oncogene (now called *THRA2*) has been identified as the a_2 thyroid hormone receptor in the brain and hypothalamus. Thyroid hormone receptors consist of a ligand-binding domain (binds T_3), hinge region, and DNA-binding domain (zinc finger). Binding of

T_3 activates the thyroid hormone receptor response element, resulting in production of an encoded mRNA and protein synthesis and of secretion specific for the target cell. In this manner, a single hormone, T_4 , acting through tissue-specific thyroid hormone receptor isoforms and gene-specific thyroid response elements, can produce multiple effects in various tissues.

About 70% of the circulating T_4 is firmly bound to *thyroxine-binding globulin* (TBG). Less important carriers are thyroxine-binding prealbumin, called *transthyretin*, and albumin. Only 0.03% of T_4 in serum is not bound and comprises free T_4 . Approximately 50% of circulating T_3 is bound to TBG, and 50% is bound to albumin; 0.30% of T_3 is unbound or free T_3 . Because the concentration of TBG is altered in many clinical circumstances, its status must be considered when interpreting T_4 or T_3 levels.

THYROID REGULATION

The thyroid is regulated by TSH, a glycoprotein produced and secreted by the anterior pituitary. This hormone activates adenylate cyclase in the thyroid gland to effect release of thyroid hormones. TSH is composed of two noncovalently bound subunits (chains): a and ß. The a subunit is common to luteinizing hormone, follicle-stimulating hormone, and chorionic gonadotropin; the specificity of each hormone is conferred by the ß subunit. TSH synthesis and release are stimulated by TSH-releasing hormone (TRH), which is synthesized in the hypothalamus and secreted into the pituitary. TRH is found in other parts of the brain besides the hypothalamus and in many other organs; aside from its endocrine function, it may be a neurotransmitter. TRH is a simple tripeptide. In states of decreased production of thyroid hormone, TSH and TRH are increased. Exogenous thyroid hormone or increased thyroid hormone synthesis inhibits TSH and TRH production. Except in the neonate, levels of TRH in serum are very low.

Further control of the level of circulating thyroid hormones occurs in the periphery. In many nonthyroidal illnesses, extrathyroidal production of T_3 decreases; factors that inhibit thyroxine-5'-deiodinase include fasting, chronic malnutrition, acute illness, and certain drugs. Levels of T_3 may be significantly decreased, whereas levels of free T_4 and TSH remain normal. Presumably, the decreased levels of T_3 result in decreased rates of oxygen production, of substrate use, and of other catabolic processes.

557.1 Thyroid Hormone Studies

Serum Thyroid Hormones.

Methods are available to measure all of the thyroid hormones in sera: T_4 , free T_4 , T_3 , free T_3 , and the diiodothyronines. A metabolically inert T_3 (3,5', 3'-triiodothyronine), called reverse T_3 , is also present in sera. Age must be considered in interpreting results, particularly in the neonate.

Thyroglobulin is a glycoprotein dimer that is secreted through the apical surface of the thyrocyte into the colloid. Small amounts escape into the circulation and are measurable in serum. Levels increase with TSH (also called thyrotropin) stimulation and decrease with TSH suppression. Levels are increased in the neonate, in patients with Graves disease and other forms of autoimmune thyroid disease, and in those with endemic goiter. The most marked elevations of thyroglobulin occur in patients with differentiated carcinoma of the thyroid. Athyreotic infants may have markedly reduced levels of thyroglobulin in serum.

TSH levels in serum are an extremely sensitive indicator of primary hypothyroidism. A 3rd generation of assays (chemiluminescent assays) that can measure complete suppression of TSH below the normal range is standard. After the neonatal period, normal levels of TSH are less than 6?µU/mL. These sensitive TSH assays obviate the need for TRH stimulation in the diagnosis of most patients with thyroid disorders.

Fetal and Newborn Thyroid.

Fetal serum T_4 increases progressively from midgestation to approximately 11.5?µg/dL at term. Fetal levels of T_3 are low before 20 wk and then gradually increase to about 45?ng/dL at term. Reverse T_3 levels, however, are very high in the fetus (250?ng/dL at 30 wk) and decrease to 150?ng/dL at term. Serum levels of TSH gradually increase to 10?mU/L at term. Approximately one third of maternal T_4 crosses the placenta to the fetus. Maternal T_4 may play a role in fetal development, especially that of the brain, before the synthesis of fetal thyroid hormones begins. The fetus of a hypothyroid mother may be at risk for neurologic damage, and a hypothyroid fetus may be partially protected by maternal T_4 until delivery.

At birth, there is an acute release of TSH; peak serum concentrations reach 60?mU/L in 30?min in full-term infants. A rapid decline occurs in the ensuing 24?hr and a more gradual decline within the next 5 days to less than 10?µU/mL. The acute increase in TSH produces a dramatic increase in levels of T_4 to approximately 16?µg/dL and of T_3 to approximately 300?ng/dL in about 4?hr. This T_3 seems largely derived from increased peripheral conversion of T_4 to T_3 . T_4 levels gradually decrease during the first 2 wk of life to 12?µg/dL. T_3 levels then decline during the 1st wk of life to levels under 200?ng/mL. Serum free T3 concentrations are approximately 540?pg/dL in infancy and decline to 210–440?pg/dL in childhood. Reverse T_3 levels are maintained for 2 wk (200?ng/dL) and decrease by 4 wk to around 50?ng/dL. The amount of T_4 that crosses the placenta is not sufficient to interfere with a diagnosis of congenital hypothyroidism in the neonate.

Serum Thyroxine-Binding Globulin.

The thyroid hormones are transported in plasma bound to TBG, a glycoprotein synthesized in the liver. Estimation of TBG levels is occasionally necessary because TBG is increased or decreased in a variety of clinical situations, with effects on the level of total thyroxine. TBG binds about 70% of T_4 and 50% of T_3 . TBG levels increase in pregnancy and in the newborn period, and with administration of estrogens (oral contraceptives), perphenazine, and heroin, and decrease with androgens, anabolic steroids, glucocorticoids, and l-asparaginase. These effects are the results of modulation of hepatic synthesis of TBG. Phenytoin (diphenylhydantoin) is another cause of drug-induced abnormality of thyroid function tests. Phenytoin, an inducer of hepatic enzymes, stimulates hepatic degradation of T_4 and accelerates transport of T_4 into tissues. Phenobarbital and carbamazepine have a similar effect. Some drugs, particularly phenytoin, also inhibit binding of T_4 and T_3 to TBG. Decreased or increased levels of TBG also occur as genetic traits (see Chapter 558). TBG levels may be markedly decreased owing to decreased production with liver disease or loss in the urine, as in the congenital nephrotic syndrome.

In Vivo Radionuclide Studies.

Markedly improved direct tests of thyroid function have made radioiodine uptake studies less useful. The iodine-trapping or concentrating mechanism of the thyroid can be evaluated by measuring the uptake of radioactive isotope ^{123}I (half-life of 13?hr). The technology allows doses of radioiodine (0.1–0.5?mCi) that are only a fraction of those

---

formerly used with ^{131}I. Technetium (^{99m}Tc) is a particularly useful radioisotope for children, because in contrast to iodine, it is trapped but not organified by the thyroid and has a half-life of only 6?hr. Thyroid scanning may be indicated to assess the presence of thyroid tissue in questions of thyroid agenesis, to detect ectopic thyroid tissue, or to evaluate possible “hot” thyroid nodules. These studies should be performed with ^{99m}Tc as pertechnetate because it has the advantages of lower radiation exposure and high-quality scintigrams. Use of ^{131}I in children should be limited to those known to have thyroid cancer.

Thyroid Ultrasonographic Studies.

Thyroid ultrasound examinations can determine the location, size, and shape of the thyroid gland, and they can assess the solid or cystic nature of nodules. Ultrasound is not as reliable as radionuclide studies in evaluating infants with suspected thyroid dysgenesis, particularly ectopic glands. Ultrasound examinations are very useful in identifying normal thyroid gland position in children with suspected thyroglossal duct cysts. In children with autoimmune thyroiditis, ultrasound reveals scattered hypoechogenicity. Ultrasound examinations are more accurate than physical

examination in estimating goiter size and assessing thyroid nodules.

Chapter 558 - Defects of Thyroxine-Binding Globulin

Abnormalities in levels of thyroxine-binding globulin (TBG) are not associated with clinical disease and do not require treatment. They are usually uncovered by a chance finding of abnormally low or high levels of thyroxine (T_4) and may be a source of confusion in the diagnosis of hypothyroidism or hyperthyroidism.

TBG deficiency occurs as an X-linked dominant disorder. Congenital TBG deficiency is most often discovered through screening programs for neonatal hypothyroidism that use levels of T_4 as the primary screen. Affected patients have low levels of T_4 and elevated resin triiodothyronine uptake (RT_3 U), but levels of free T_4 and thyroid-stimulating hormone (TSH) are normal. The diagnosis is confirmed by the finding of absent or low levels of TBG. The disorder is more readily recognized in male patients because it is caused by a gene on the short arm of the X chromosome. TBG deficiency occurs in 1 in 2,400 male newborns, 36% of whom have TBG levels less than 1?mg/dL. Milder forms of TBG deficiency occur in approximately 1/42,000 heterozygous female newborns. Complete TBG deficiency (<5?µg/dL) occurs much less frequently. Three of eight families with complete TBG deficiency have been found to have a codon mutation (leucine to proline); other patients with reduced affinity of TBG for T_4 have had other point mutations that affect the tertiary structure of the protein. Acquired TBG deficiency occurs with androgen and glucocorticoid treatment, hepatic insufficiency (not hepatitis), and renal disease and proteinuria.

TBG excess is also a harmless X-linked dominant anomaly, occurring in about 1/25,000 persons. It has been recognized primarily in adults, but neonatal screening programs uncover the condition in the neonate. The level of T_4 is elevated, T_3 is variably elevated, TSH and free T_4 are normal, and RT_3 U is decreased. The elevated levels of TBG confirm the diagnosis. In neonates, levels of T_4 as high as 95?µg/dL have been found, which decrease to 20–30?µg/dL after 2–3 wk. Such high levels of T_4 are thought to be related in part to the normally elevated levels of TBG in neonates during the 1st mo of life, presumably as an effect of maternal estrogens. Affected patients are euthyroid. Family studies may be indicated to alert other affected individuals. Acquired elevations of TBG occur with pregnancy, estrogen treatment, and hepatitis.

Familial dysalbuminemic hyperthyroxinemia is an autosomal dominant disorder that may be confused with hyperthyroidism. Markedly increased binding of T_4 to an abnormal albumin variant leads to increased serum concentrations of T_4 . However, the levels of free T_4 , free T_3 , and TSH are normal. Levels of T_3 are normal or only

slightly elevated. Affected patients are euthyroid.

Chapter 559 - Hypothyroidism

Hypothyroidism results from deficient production of thyroid hormone or a defect in thyroid hormonal receptor activity (Box 559–1). The disorder may be manifested from birth. When symptoms appear after a period of apparently normal thyroid function, the disorder may be truly "acquired" or may only appear so as a result of one of a variety of congenital defects in which the manifestation of the deficiency is delayed. The term *cretinism* is often used synonymously with congenital hypothyroidism but should be avoided.

CONGENITAL HYPOTHYROIDISM

Congenital causes of hypothyroidism may be sporadic or familial, goitrous or nongoitrous. In many cases, the deficiency of thyroid hormone is severe, and symptoms develop in the early weeks of life. In others, lesser degrees of deficiency occur, and manifestations may be delayed for months.

Epidemiology.

The prevalence of congenital hypothyroidism based on nationwide programs for neonatal screening is 1/4,000 infants worldwide; prevalence is lower in black Americans (1/32,000) and higher in Hispanics and Native Americans (1/2,000). Twice as many girls as boys are affected.

Etiology

THYROID DYSGENESIS.

Some form of thyroid dysgenesis (aplasia, hypoplasia, or an ectopic gland) is the most common cause of congenital hypothyroidism, accounting for 85% of cases; 10% are caused by an inborn error of thyroxine synthesis, and 5% are the result of transplacental maternal thyrotropin-receptor blocking antibody. In about one third of cases of dysgenesis, even sensitive radionuclide scans can find no remnants of thyroid tissue *(aplasia)*. In the other two thirds of infants, rudiments of thyroid tissue are found in an ectopic location, anywhere from the base of the tongue *(lingual thyroid)* to the normal position in the neck *(hypoplasia)*.

Thyroid dysgenesis occurs sporadically, but familial cases have occasionally been reported. In neonates with congenital hypothyroidism due to thyroid dysgenesis, 2% of cases are familial; thus, 98% are sporadic.

Box 559-1. Etiologic Classification of Congenital Hypothyroidism

CENTRAL (HYPOPITUITARY) HYPOTHYROIDISM

- Pit-1 (homeobox protein) mutations
  - Deficiency of thyrotropin, growth hormone, and prolactin
- Prop-1 mutations
  - Deficiency of thyrotropin, growth hormone, prolactin, LH, FSH, ±ACTH
- Thyrotropin-releasing hormone (TRH) deficiency
  - Isolated?
  - Multiple hypothalamic deficiencies (e.g., craniopharyngioma)
- TRH unresponsiveness
  - Mutations in TRH receptor
- Thyrotropin (TSH) deficiency
  - Mutations in ß-chain
  - Multiple pituitary deficiencies
- Thyrotropin unresponsiveness
  - G_s a mutation (e.g., type IA pseudohypoparathyroidism)
  - Mutation in TSH receptor

PRIMARY HYPOTHYROIDISM

Mutation in TSH receptor

PRIMARY HYPOTHYROIDISM

- Defect of fetal thyroid development
  - Aplasia, ectopia (dysgenesis)
- Defect in thyroid hormone synthesis (e.g., goitrous hypothyroidism)
  - Thyroid oxidase mutations: homozygotic—permanent; heterozygotic—transient
  - Iodide transport defect
  - Thyroid peroxidase defect
  - Thyroglobulin synthesis defect
  - Deiodination defect
- Iodine deficiency (endemic goiter)
  - Neurologic type
  - Myxedematous type
- Maternal antibodies
  - Thyrotropin receptor–blocking antibody (TRBAb) (also termed thyrotropin binding inhibitor immunoglobulin)
- Maternal medications
  - Radioiodine, iodides
  - Propylthiouracil, methimazole
  - Amiodarone

LH = luteinizing hormone; FSH = follicle-stimulating hormone; ACTH = adrenocorticotropic hormone

The exact cause of thyroid dysgenesis is unknown in most cases. Three transcription factors, TTF-1, TTF-2, and PAX-8, are important for thyroid morphogenesis and differentiation; of 98 neonates with congenital hypothyroidism, two had mutations in

the PAX-8 gene. One infant had thyroid ectopy, whereas the other had thyroid hypoplasia. Two siblings have been reported with thyroid agenesis and mutations in the gene for TTF-2; they also had a cleft lip and choanal atresia.

The frequent finding of thyroid dysgenesis confined to only one of a pair of monozygotic twins suggests the operation of a deleterious factor during intrauterine life. Maternal antithyroid antibodies might be that factor, especially because antibodies in patients with autoimmune thyroid disease belong predominantly to the IgG class and can cross the placenta. Although thyroid peroxidase (TPO) antibodies have been detected in some mother-infant pairs, there is little evidence of their pathogenicity. The demonstration of thyroid growth-blocking and cytotoxic antibodies in some infants with thyroid dysgenesis, as well as in their mothers, suggests a more likely pathogenetic mechanism.

Ectopic thyroid tissue (lingual, sublingual, subhyoid) may provide adequate amounts of thyroid hormone for many years or may fail in early childhood. Affected children come to clinical attention because of a growing mass at the base of the tongue or in the midline of the neck, usually at the level of the hyoid. Occasionally, ectopia is associated with thyroglossal duct cysts. It may occur in siblings. Surgical removal of ectopic thyroid tissue from a euthyroid individual usually results in hypothyroidism, because most such patients have no other thyroid tissue. Newborn screening programs may detect these patients and avoid delayed diagnosis.

DEFECTIVE SYNTHESIS OF THYROXINE.

A variety of defects in the biosynthesis of thyroid hormone may result in congenital hypothyroidism; when the defect is incomplete, compensation occurs, and onset of hypothyroidism may be delayed for years. A goiter is almost always present, and the defect is detected in 1/30,000–50,000 live births in neonatal screening programs. These defects are transmitted in an autosomal recessive manner.

DEFECT OF IODIDE TRANSPORT.

This rare defect has been reported in nine related infants of the Hutterite sect, and about half the cases are from Japan. Consanguinity has occurred in about one third of the families. It almost certainly involves mutations in the gene coding for the sodium-iodine symporter. In the past, clinical hypothyroidism, with or without a goiter, often developed in the first few months of life; the condition has been detected in neonatal screening programs. In Japan, however, untreated patients acquire goiter and hypothyroidism after 10 yr of age, perhaps because of the very high iodine content (often 19?mg/24?hr) of the Japanese diet.

The energy-dependent mechanisms for concentrating iodide are defective in the thyroid and salivary glands. In contrast to other defects of thyroid hormone synthesis, uptake of radioiodine and pertechnetate is low; a saliva:serum ratio of ^{123}I may be required to establish the diagnosis. This condition responds to treatment with large doses of potassium iodide, but treatment with thyroxine (T_4) is preferable.

THYROID PEROXIDASE DEFECTS OF ORGANIFICATION AND COUPLING.

This is the most common of the T_4 synthetic defects. After iodide is trapped by the thyroid, it is rapidly oxidized to reactive iodine, which is then incorporated into tyrosine units. This process requires generation of H_2O_2, thyroid peroxidase, and hematin (an enzyme cofactor); defects can involve each of these components, and there is considerable clinical and biochemical heterogeneity. In the Dutch neonatal screening program, 23 infants were found with a complete organification defect (1/60,000), but its prevalence in other areas is unknown. A characteristic finding in all patients with this defect is a marked decrease in thyroid radioactivity when perchlorate or thiocyanate is administered 2?hr after administration of a test dose of radioiodine. In these patients, perchlorate discharges 40–90% of radioiodine compared with less than 10% in normal individuals. Several mutations in the TPO gene have been reported in children with congenital hypothyroidism. Patients with Pendred syndrome, a disorder comprising sensorineural deafness and goiter, also have a positive perchlorate discharge. **Pendred syndrome** appears to be due to a defect in a sulfate transport protein common to the thyroid gland and the cochlea.

Thyroid oxidase 2 helps generate H_2O_2. Bi-allelic inactivating mutations produce permanent congenital hypothyroidism, whereas single gene lesions produce transient hypothyroidism.

DEFECTS OF THYROGLOBULIN SYNTHESIS.

This heterogeneous group of disorders, characterized by goiter, elevated thyroid-stimulating hormone (TSH), low T_4 levels, and absent or low levels of thyroglobulin (TG), has been reported in approximately 100 patients. Studies in animal models with congenital goiter have disclosed point mutations of the gene for TG in Afrikaner cattle and in Dutch goitrous goats. Analogous molecular defects have been described in a few patients.

DEFECTS IN DEIODINATION.

Monoiodotyrosine and diiodotyrosine released from thyroglobulin are normally deiodinated within the thyroid or in peripheral tissues by a deiodinase. The liberated iodine is recycled in the synthesis of TG. Patients with a deficiency of this enzyme experience severe iodine loss from the constant urinary excretion of nondeiodinated tyrosines, leading to hormonal deficiency and goiter. The deiodination defect may be limited to thyroid tissue only or to peripheral tissue only, or it may be universal.

THYROTROPIN RECEPTOR-BLOCKING ANTIBODY.

Thyrotropin receptor-blocking antibody (TRBAb) is called *thyroid-binding inhibitor immunoglobulin.* An unusual cause of transitory congenital hypothyroidism is the transplacental passage of maternal antibodies that inhibit binding of TSH to its receptor in the neonate. The frequency is approximately 1/50,000–100,000 infants. It should be suspected whenever there is a history of maternal autoimmune thyroid

disease, including Hashimoto thyroiditis, Graves disease, hypothyroidism while the patient is receiving replacement therapy, or recurrent congenital hypothyroidism of a transient nature in subsequent siblings. In these situations, maternal levels of TRBAb should be measured during pregnancy. Affected infants and their mothers often also have thyrotropin receptor-stimulating antibodies and TPO antibodies. Technetium pertechnetate and ^{125}I scans may fail to detect any thyroid tissue, mimicking thyroid agenesis, but after the condition remits, a normal thyroid gland is demonstrable following discontinuation of replacement treatment. The half-life of the antibody is 21 days, and remission of the hypothyroidism occurs in about 3 mo. Correct diagnosis of this cause of congenital hypothyroidism prevents protracted unnecessary treatment, alerts the clinician to possible recurrences in future pregnancies, and allows a favorable prognosis.

RADIOIODINE ADMINISTRATION.

Hypothyroidism has been reported as a result of inadvertent administration of radioiodine during pregnancy for treatment of Graves disease or cancer of the thyroid. Although only a few affected infants have been reported, a 1976 mail survey of endocrinologists uncovered 237 cases of women who had inadvertently received therapeutic doses of ^{131}I during the 1st trimester of pregnancy. The fetal thyroid is capable of trapping iodide by 70–75 days. Whenever radioiodine is administered to a woman of childbearing age, a pregnancy test must be performed before a therapeutic dose of ^{131}I is given, regardless of the menstrual history or putative history of contraception. Administration of radioactive iodine to lactating women is also contraindicated because it is readily excreted in milk.

THYROTROPIN DEFICIENCY.

Deficiency of TSH and hypothyroidism may occur in any of the conditions associated with developmental defects of the pituitary or hypothalamus (see Chapter 551). More often in these conditions, the deficiency of TSH is secondary to a deficiency of thyrotropin-releasing hormone (TRH). TSH-deficient hypothyroidism is found in 1/30,000–50,000 infants, but only 30–40% of these cases are detected by neonatal thyroid screening. The majority of affected infants have multiple pituitary deficiencies and present with hypoglycemia, persistent jaundice, and micropenis in association with septo-optic dysplasia, midline cleft lip, midface hypoplasia, and other midline facial anomalies.

Pit-1 mutations are a recessive cause of hypothyroidism secondary to TSH deficiency. Affected children also have deficiency of growth hormone and prolactin. Pit-1, a gene transcription factor, is essential to differentiation, maintenance, and proliferation of somatotrophs, lactotrophs, and thyrotrophs. Examination of prolactin and TSH responses to TRH stimulation can detect these patients. Failure of the prolactin response to TRH should prompt examination of the Pit-1 gene.

Isolated deficiency of TSH is a rare autosomal recessive disorder that has been reported in five sibships. DNA studies in two Japanese children and in three children in two related Greek families have revealed different point mutations in the TSH ß subunit gene; studies in two German siblings revealed a mutation causing a stop codon due to a frame shift.

A mutation in the TSH-receptor gene has been reported in three siblings with elevated levels of TSH and normal levels of T_4 ; two of them had been detected during neonatal screening. Despite persistent resistance to TSH through childhood, they remained euthyroid without treatment. Patients in three other reports of presumed TSH-receptor gene mutations had severe hypothyroidism that required treatment. The disorder is inherited in an autosomal recessive fashion. Both homozygous and compound heterozygous mutations in the TSH receptor gene have been reported.

THYROTROPIN HORMONE UNRESPONSIVENESS.

Mild congenital hypothyroidism has been detected in newborn infants who subsequently proved to have type Ia pseudohypoparathyroidism. The molecular cause of resistance to TSH in these patients is the generalized impairment of cyclic adenosine monophosphate activation caused by genetic deficiency of the a subunit of the guanine nucleotide regulatory protein, G_s (see Chapter 566).

Several instances of isolated TSH unresponsiveness have been detected. Serum levels of T_4 were low, those of TSH by radioimmunoassay and bioassay were elevated, and there was no response to exogenous TSH administration.

THYROTROPIN-RELEASING HORMONE ABNORMALITY.

A patient with a TRH receptor abnormality resulting in isolated TSH deficiency and hypothyroidism has been reported. This condition was suspected because of failure of both TSH and prolactin to respond to TRH stimulation. Investigations disclosed a compound heterozygote mutation in the gene coding for the TRH receptor, resulting in inability of the receptor to bind TRH.

THYROID HORMONE UNRESPONSIVENESS.

An increasing number of patients are being found with resistance to the actions of endogenous and exogenous T_4 and triiodothyronine (T_3). Most patients have goiter, and levels of T_4 , T_3 , free T_4 , and free T_3 are elevated. These findings have often led to the erroneous diagnosis of Graves disease, although most affected patients are clinically euthyroid. The unresponsiveness may vary among tissues. There may be subtle clinical features of hypothyroidism, including mild mental retardation, growth retardation, and delayed skeletal maturation. One neurologic manifestation is an increased association of attention-deficit hyperactivity disorder; the converse is not true, however, because individuals with attention-deficit hyperactivity disorder do not have an increased risk of thyroid hormone resistance. It is presumed that these patients have varying tissue resistance to thyroid hormone. TSH levels are diagnostic in that they are not suppressed as in Graves disease but instead are moderately elevated or normal but inappropriate for the levels of T_4 and T_3 when measured by a sensitive TSH assay. A TSH response to TRH occurs in these patients, unlike the situation in Graves disease. The failure of TSH suppression indicates that the resistance is generalized and affects the pituitary gland as well as peripheral tissues. The disorder is most often inherited in an autosomal dominant

fashion. More than 40 distinct point mutations in the hormone-binding domain of the ß-thyroid receptor have been identified. Different phenotypes do not correlate with genotypes. The same mutation has been observed in individuals with generalized or isolated pituitary resistance, even in different individuals of the same family. A child homozygous for the receptor mutation showed unusually severe resistance. These cases support the dominant negative effect of mutant receptors, in which the mutant receptor protein inhibits normal receptor action in heterozygotes. Elevated levels of T_4 on neonatal thyroid screening should suggest the possibility of this diagnosis. No treatment is usually required unless growth and skeletal retardation are present.

Two infants of consanguineous matings are known to have an autosomal recessive form of thyroid resistance. These infants had manifestations of hypothyroidism early in life, and DNA studies revealed a major deletion of the ß-thyroid receptor in one individual. The resistance appears to be more severe in this form of the entity.

On rare occasions, resistance to thyroid hormone may selectively affect the pituitary gland. Because the peripheral tissues

are not resistant to thyroid hormones, the patient presents with a goiter and manifestations of hyperthyroidism. The laboratory findings are the same as those seen with generalized thyroid hormone resistance. This condition must be differentiated from a pituitary TSH-secreting tumor. At least one young child has been successfully treated with D-thyroxine therapy. Bromocriptine administration, which interferes with TSH secretion, was reported to be successful in another patient.

IODINE EXPOSURE.

Congenital hypothyroidism may result from fetal exposure to excessive iodides or antithyroid drugs. Perinatal exposure may occur with the use of iodine antiseptic to prepare the skin for cesarian section or painting of the cervix prior to delivery. These conditions are transitory and must not be mistaken for the other forms of hypothyroidism described. In the neonate, topical iodine-containing antiseptics used in nurseries and by surgeons can also cause transient congenital hypothyroidism, especially in low birthweight infants, and can lead to abnormal results on neonatal screening tests. In older children, the usual sources of iodides are proprietary preparations used to treat asthma. In a few instances, the cause of hypothyroidism was amiodarone, an antiarrhythmic drug with high iodine content. In most of these instances goiter is present (see Chapter 561.3).

IODINE DEFICIENCY-ENDEMIC GOITER.

Essentially unseen in the United States, iodine deficiency or endemic goiter is the most common cause of congenital hypothyroidism worldwide. Borderline iodine deficiency is more likely to cause problems in preterm infants who depend on a maternal source of iodine.

THYROID FUNCTION IN PRETERM BABIES.

Postnatal thyroid function in preterm babies is qualitatively similar but quantitatively reduced compared with that of term infants. The cord serum T_4 is decreased in proportion to gestational age and birthweight. The postnatal TSH surge is reduced, and infants with complications of prematurity, such as respiratory distress syndrome, actually experience a decrease in serum T_4 in the 1st week of life. As these complications resolve, the serum T_4 gradually increases so that generally by 6 wk of life it enters the T_4 range seen in term infants. Serum free T_4 concentrations seem less affected, and when measured by equilibrium dialysis, these levels are often normal. Preterm babies also have a higher frequency of transient TSH elevations and apparent transient primary hypothyroidism. Premature infants less than 28 wk of gestation may have problems resulting from a combination of immaturity of the hypothalamic-pituitary-thyroid axis and loss of the maternal contribution of thyroid hormone and so may be candidates for temporary thyroid hormone replacement; further studies on this issue are needed.

Clinical Manifestations.

Most infants with congenital hypothyroidism are asymptomatic at birth, even if there is complete agenesis of the thyroid gland. This situation is attributed to the transplacental passage of moderate amounts of maternal T_4 , which provides fetal levels that are 33% of normal at birth. These low serum levels of T_4 and concomitantly elevated levels of TSH make it possible to screen and detect most hypothyroid neonates.

The clinician is dependent on neonatal screening tests for diagnosis of congenital hypothyroidism. Laboratory errors occur, however, and awareness of early symptoms and signs must be maintained. Congenital hypothyroidism is twice as common in girls as in boys. Before neonatal screening programs, congenital hypothyroidism was rarely recognized in the newborn because the signs and symptoms are usually not sufficiently developed. It can be suspected and the diagnosis established during the early weeks of life if the initial but less characteristic manifestations are recognized. Birthweight and length are normal, but head size may be slightly increased because of myxedema of the brain. Prolongation of physiologic icterus, caused by delayed maturation of glucuronide conjugation, may be the earliest sign. Feeding difficulties, especially sluggishness, lack of interest, somnolence, and choking spells during nursing, are often present during the 1st mo of life. Respiratory difficulties, due in part to the large tongue, include apneic episodes, noisy respirations, and nasal obstruction. Typical respiratory distress syndrome may also occur. Affected infants cry little, sleep much, have poor appetites, and are generally sluggish. There may be constipation that does not usually respond to treatment. The abdomen is large, and an umbilical hernia is usually present. The temperature is subnormal, often less than 35°C (95°F), and the skin, particularly that of the extremities, may be cold and mottled. Edema of the genitals and extremities may be present. The pulse is slow, and heart murmurs, cardiomegaly, and asymptomatic pericardial effusion are common. Anemia (macrocytic) is often present and is refractory to treatment with hematinics. Because

symptoms appear gradually, the diagnosis is often delayed.

These manifestations progress; retardation of physical and mental development becomes greater during the following months, and by 3–6 mo of age, the clinical picture is fully developed (Fig. 559–1). When there is only a partial deficiency of thyroid hormone, the symptoms may be milder, the syndrome incomplete, and the onset delayed. Although breast milk contains significant amounts of thyroid hormones, particularly T_3 , it is inadequate to protect the breast-fed infant with congenital hypothyroidism, and it has no effect on neonatal thyroid screening tests.

The child's growth is stunted, the extremities are short, and the head size is normal or even increased. The anterior and posterior fontanels are open widely; observation of this sign at birth may serve as an initial clue to the early recognition of congenital hypothyroidism. Only 3% of normal newborn infants have a posterior fontanel larger than 0.5?cm. The eyes appear far apart, and the bridge of the broad nose is depressed. The palpebral fissures are narrow and the eyelids swollen. The mouth is kept open, and the thick and broad tongue protrudes from it. Dentition is delayed. The neck is short and thick, and there may be deposits of fat above the clavicles and between the neck and shoulders. The hands are broad and the fingers short. The skin is dry and scaly, and there is little perspiration. Myxedema is manifested, particularly in the skin of the eyelids, the back of the hands, and the external genitals. Carotenemia may cause a yellow discoloration of the skin, but the scleras remain white. The scalp is thickened, and the hair is coarse, brittle, and scanty. The hairline reaches far down on the forehead, which usually appears wrinkled, especially when the infant cries.

Development is usually retarded. Hypothyroid infants appear lethargic and are late in learning to sit and stand. The voice is hoarse, and they do not learn to talk. The degree of physical and mental retardation increases with age. Sexual maturation may be delayed or may not take place at all.

The muscles are usually hypotonic, but in rare instances generalized muscular pseudohypertrophy occurs *(Kocher-Debré-Sémélaigne syndrome)*. Affected children may have an athletic appearance because of pseudohypertrophy, particularly in the calf muscles. Its pathogenesis is unknown; nonspecific histochemical and ultrastructural changes seen on muscle biopsy return to normal with treatment. Boys are more prone to development of the syndrome, which has been observed in siblings born to a consanguineous mating. Affected patients have hypothyroidism of longer duration and severity.

Laboratory Findings.

Most newborn screening programs in North America measure levels of T_4 , supplemented by measurement of TSH when T_4 is low. This approach identifies infants with primary hypothyroidism, those with low levels of thyroxine-binding globulin, some with hypothalamic or pituitary hypothyroidism, and infants with a delayed increase in TSH levels.

Figure 559-1 Congenital hypothyroidism in an infant 6 mo of age. The infant ate poorly in the neonatal period and was constipated. She had a persistent nasal discharge and a large tongue; she was very lethargic; she had no social smile and no head control. *A,* Notice the puffy face, dull expression, and hirsute forehead. Tests revealed a negligible uptake of radioiodine. Osseous development was that of a newborn. *B,* Four mo after treatment, notice the decreased puffiness of the face, the decreased hirsutism of the forehead, and the alert appearance.

European and Japanese neonatal screening programs are based on a primary measurement of TSH; some North American programs are switching to primary TSH screening. This approach detects infants with primary hypothyroidism and may detect infants with subclinical hypothyroidism (normal T_4 , elevated TSH), but it misses infants with delayed TSH elevation, low thyroxine-binding globulin levels, and hypothalamic or pituitary hypothyroidism. With any of these assays, special care should be given to the normal range of values for age of the patient, particularly in the first weeks of life. Regardless of the approach used for screening, some infants escape detection because of technical or human errors; clinicians must maintain their vigilance for clinical manifestations of hypothyroidism.

Serum levels of T_4 or free T_4 are low; serum levels of T_3 may be normal and are not helpful in the diagnosis. If the defect is primarily in the thyroid, levels of TSH are elevated, often to greater than 100?mU/L. Serum levels of prolactin are elevated, correlating with those of TSH. Serum levels of TG are usually low in infants with thyroid agenesis or defects of TG synthesis or secretion, but they may be elevated with ectopic glands and other inborn errors of thyroxine synthesis.

Special attention should be paid to identical twins, because in at least four cases neonatal screening failed to detect the discordant twin with hypothyroidism, and the diagnosis was not made until the infants were 4–5 mo of age. Apparently, transfusion of euthyroid blood from the unaffected twin normalized the serum level of T_4 and TSH in the affected twin at the initial screening.

Retardation of osseous development can be shown roentgenographically at birth in about 60% of congenitally hypothyroid infants and indicates some deprivation of thyroid hormone during intrauterine life. For example, the distal femoral epiphysis, normally present at birth, is often absent (Fig. 559–2*A*). In untreated patients, the discrepancy between chronological age and osseous development increases. The epiphyses often have multiple foci of ossification (epiphyseal dysgenesis, Fig. 559–2*B*); deformity ("breaking") of the 12th thoracic or 1st or 2nd lumbar vertebra is common. Roentgenograms of the skull show large fontanels and wide sutures; intersutural (wormian) bones are common. The sella turcica is often enlarged and round; in rare instances there may be erosion and thinning. Delays in formation and eruption of teeth may occur. Cardiac enlargement or pericardial effusion may be present.

Scintigraphy can help to pinpoint the underlying cause in infants with congenital hypothyroidism, but treatment should not be unduly delayed for this study. ^{123}I-sodium iodide is superior to ^{99m}Tc-sodium pertechnetate for this purpose.

Ultrasonographic examination of the thyroid is helpful, but studies show it may miss some ectopic glands shown by scintigraphy. Serum levels of TG are low with agenesis and elevated with ectopic glands and goiters, but there is a wide overlap of ranges. Demonstration of ectopic thyroid tissue is diagnostic of thyroid dysgenesis and establishes the need for lifelong treatment with T_4 . Failure to demonstrate any thyroid tissue suggests thyroid aplasia, but this also occurs in neonates with TRBAb and in infants with the iodide-trapping defect. A normally situated thyroid gland with a normal or avid uptake of radionuclide indicates a defect in thyroid hormone biosynthesis. Patients with goitrous hypothyroidism may require extensive evaluation, including radioiodine studies, perchlorate discharge tests, kinetic studies, chromatography, and studies of thyroid tissue, if the biochemical nature of the defect is to be determined.

The electrocardiogram may show low-voltage P and T waves with diminished amplitude of QRS complexes and suggest poor left ventricular function and pericardial effusion. The electroencephalogram frequently shows low voltage. In children older than 2 yr of age, the serum cholesterol level is usually elevated. Brain MRI before treatment is reportedly normal, although proton magnetic resonance spectroscopy shows high levels of choline-containing compounds, which may reflect blocks in myelin maturation.

Treatment.

Sodium-L-thyroxine given orally is the treatment of choice. Because 80% of circulating T_3 is formed by monodeiodination of T_4 , serum levels of T_4 and T_3 in treated infants return to normal. This is also true in the brain, where 80% of required T_3 is produced locally from T_4 . In neonates, the initial starting dose is 10–15?µg/kg (37.5 to 50?µg/24?hr). Thyroxine tablets should not be mixed with soy protein formulas or iron, because these can bind T_4 and inhibit its absorption. Levels of T_4 and TSH should be monitored at recommended intervals and maintained in the normal range for age. Children with hypothyroidism require about 4?µg/kg/24?hr, and adults require only 2?µg/kg/24?hr.

Later, confirmation of the diagnosis may be necessary for some infants to rule out the possibility of transient hypothyroidism. This is unnecessary in infants with proven thyroid ectopia or in those who manifest elevated levels of TSH after 6–12 mo of therapy because of poor compliance or an inadequate

Figure 559-2 Congenital hypothyroidism. *A,* Absence of distal femoral epiphysis in a 3-mo-old infant who was born at term. This is evidence for the onset of the hypothyroid state during fetal life. *B,* Epiphyseal dysgenesis in the head of the humerus in a 9-yr-old girl who had been inadequately treated with thyroid hormone.

dose of T_4 . Discontinuation of therapy at about 3 yr of age for 3–4 wk results in a marked increase in TSH levels in children with permanent hypothyroidism.

The only untoward effects of sodium-L-thyroxine are related to its dose. Overtreatment may risk craniosynostosis and temperament problems. An occasional older child (8–13 yr) with acquired hypothyroidism may experience pseudotumor cerebri within the first 4 mo of treatment. In older children, after catch-up growth is complete, the growth rate provides an excellent index of the adequacy of therapy. Parents should be forewarned about changes in behavior and activity expected with therapy, and special attention must be given to any developmental or neurologic deficits.

Prognosis.

With the advent of neonatal screening programs for detection of congenital hypothyroidism, the prognosis for affected infants has improved dramatically. Early diagnosis and adequate treatment from the first weeks of life result in normal linear growth and intelligence comparable with that of unaffected siblings. Some screening programs report that the most severely affected infants, as judged by the lowest T_4 levels and retarded skeletal maturation, have slightly reduced (5–10 points) IQs and other neuropsychologic sequelae, such as incoordination, hypotonia or hypertonia, short attention span, and speech problems. Approximately 20% of children have a neurosensory hearing deficit. Without treatment, affected infants become profoundly mentally deficient dwarfs. Thyroid hormone is critical for normal cerebral development in the early postnatal months; biochemical diagnosis must be made soon after birth, and effective treatment must be initiated promptly to prevent irreversible brain damage. Delay in diagnosis, failure to correct initial hypothyroxinemia rapidly, inadequate treatment, and poor compliance in the first 2–3 yr of life result in variable degrees of brain damage. When onset of hypothyroidism occurs after 2 yr of age, the outlook for normal development is much better even if diagnosis and treatment have been delayed, indicating how much more important thyroid hormone is to the rapidly growing brain of the infant.

ACQUIRED HYPOTHYROIDISM

Epidemiology.

Studies of school-aged children report that hypothyroidism occurs in approximately 0.08% (1:1,250). Acquired hypothyroidism is most commonly a result of chronic lymphocytic thyroiditis; 1.3% of children have evidence of autoimmune thyroid disease, which occurs with a 2:1 female to male preponderance.

Etiology.

The most common cause of acquired hypothyroidism (Box 559–2) is lymphocytic thyroiditis. Autoimmune thyroid disease may be part of polyglandular syndromes; children with Down, Turner, and Klinefelter syndromes and celiac disease or diabetes are at higher risk for associated autoimmune thyroid disease (see Chapter 560). Although typically seen in adolescence, it occurs as early as in the 1st yr of life. Some patients with congenital thyroid dysgenesis or with incomplete genetic defects in thyroid hormone synthesis may not display clinical manifestations until childhood and appear to have acquired hypothyroidism; these conditions are usually now detected by newborn screening programs. Subtotal thyroidectomy for

thyrotoxicosis or cancer may result in hypothyroidism, as may removal of ectopic thyroid tissue. For example, *lingual thyroid, subhyoid median thyroid*, or thyroid tissue in a *thyroglossal duct cyst* usually constitutes the only source of thyroid hormone, and excision results in hypothyroidism. Because subhyoid glands usually mimic thyroglossal duct cysts, ultrasonographic examination or a radionuclide scan before surgery is indicated in these patients.

Box 559-2. Etiologic Classification of Acquired Hypothyroidism

AUTOIMMUNE (ACQUIRED HYPOTHYROIDISM)

- Hashimoto thyroiditis
- Polyglandular autoimmune syndrome, types I, II, and III

IATROGENIC

- Propylthiouracil, methimazole, iodides, lithium, amiodarone
- Irradiation
- Radioiodine
- Radiographs (neck or whole body)
- Thyroidectomy

SYSTEMIC DISEASE

- Cystinosis
- Histiocytic infiltration

HEMANGIOMAS (LARGE) OF THE LIVER (TYPE 3 IODOTHYRONINE DEIODINASE)

RESISTANCE TO THYROID HORMONE (ONLY OCCASIONAL

HEMANGIOMAS (LARGE) OF THE LIVER (TYPE 3 IODOTHYRONINE DEIODINASE)

**RESISTANCE TO THYROID HORMONE (ONLY OCCASIONAL
CLINICAL MANIFESTATIONS OF HYPOTHYROIDISM)

Figure 559-3 *A*, Acquired hypothyroidism in a girl 6 yr of age. She was treated with a wide variety of hematinics for refractory anemia for 3 yr. She had almost complete cessation of growth, constipation, and sluggishness for 3 yr. The height age was 3 yr; the bone age was 4 yr. She had a sallow complexion and immature facies with a poorly developed nasal bridge. Serum cholesterol, 501?mg/dL; radioiodine uptake, 7% at 24?hr; PBI, 2.8?mg/dL. *B*, After therapy for 18 mo, notice the nasal development, the increased luster and decreased pigmentation of hair, and the maturation of face. The height age was 5.5 yr; the bone age was 7 yr. There was a decided improvement in her general condition. Menarche occurred at 14 yr. The ultimate height was 155?cm (61 in). She graduated from high school. The disorder was well controlled with sodium-L-thyroxine daily.

Children with *nephropathic cystinosis*, a disorder characterized by intralysosomal storage of cystine in body tissues, acquire impaired thyroid function. Hypothyroidism may be overt, but subclinical forms are more common, and periodic assessment of TSH levels is indicated. By 13 yr of age, two thirds of these patients require T_4 replacement.

Histiocytic infiltration of the thyroid in children with Langerhans cell histiocytoses may result in hypothyroidism.

Irradiation of the area of thyroid that is incidental to the treatment of Hodgkin disease or other head and neck malignancies or that is administered before bone marrow transplantation often results in thyroid damage. About one third of such children acquire elevated TSH levels within a year after therapy and 15–20% progress to hypothyroidism within 5–7 yr. Some clinicians recommend periodic TSH measurements, but others recommend treatment of all exposed patients with doses of T_4 to suppress TSH.

Protracted ingestion of medications containing iodides can cause hypothyroidism, usually accompanied by goiter (see Chapter 561). Amiodarone, a drug used for cardiac arrhythmias and consisting of 37% iodine by weight, causes hypothyroidism in about 20% of treated children. It affects thyroid function directly by its high iodine content as well as by inhibition of 5'-deiodinase, which converts T_4 to T_3 . Children treated with this drug should have serial measurements of T_4 , T_3 , and TSH.

Hypothyroidism can occur in children with large *hemangiomas* of the liver, due to increased type 3 deiodinase activity, which catalyzes conversion of T_4 to rT_3 and T_3 to T_2 . Thyroid secretion is increased but is not enough to compensate for the large increase in T_4 to rT_3 degradation.

Clinical Manifestations.

Deceleration of growth is usually the first clinical manifestation, but this sign often goes unrecognized (Fig. 559–3). Myxedematous changes of the skin, constipation, cold intolerance, decreased energy, and an increased need for sleep develop insidiously. Surprisingly, schoolwork and grades usually do not suffer, even in severely hypothyroid children. Osseous maturation is delayed, often strikingly, which is an indication of the duration of the hypothyroidism. Adolescents typically have delayed puberty, whereas younger children may present with galactorrhea or pseudoprecocious puberty. Galactorrhea is a result of increased TRH-stimulating prolactin secretion. The precocious puberty, characterized by breast development in girls and macro-orchidism in boys, is thought to be the result of abnormally high TSH concentrations binding to the follicle-stimulating hormone receptor with subsequent stimulation.

Some children present with headaches and visual problems; they usually have hyperplastic enlargement of the pituitary gland, often with suprasellar extension, after long-standing hypothyroidism; this condition, believed to be the result of thyrotroph hyperplasia, may be mistaken for a pituitary tumor (see Chapter 551).

All these changes return to normal with adequate replacement of T_4 , but in children with long-standing hypothyroidism, catch-up growth may be incomplete. During the first 18 mo of treatment, skeletal maturation often exceeds expected linear growth, resulting in a loss of about 7?cm of predicted adult height. The cause for this is unknown.

Diagnostic Studies and Treatment.

Treatment and diagnostic studies are the same as those described for congenital hypothyroidism. Measurement of antithyroglobulin and antiperoxidase (formerly antimicrosomal) antibodies may pinpoint autoimmune thyroiditis as the cause. During the 1st yr of treatment, deterioration of schoolwork, poor sleeping habits, restlessness, short attention span, and behavioral problems may ensue, but these are transient; forewarning families about these manifestations enhances appropriate management. These may be partially ameliorated by starting at subreplacement T_4 doses and advancing slowly.

Chapter 560 - Thyroiditis

LYMPHOCYTIC THYROIDITIS (HASHIMOTO THYROIDITIS; AUTOIMMUNE THYROIDITIS)

Lymphocytic thyroiditis is the most common cause of thyroid disease in children and adolescents and accounts for many of the enlarged thyroids formerly designated “adolescent” or “simple” goiter. It is also the most common cause of acquired hypothyroidism, with or without goiter. There are 1.3% of school-aged children who have evidence for autoimmune thyroid disease.

Etiology.

This typical organ-specific autoimmune disease is characterized histologically by lymphocytic infiltration of the thyroid. Early in the course of the disease, there may be hyperplasia only; this is followed by infiltration of lymphocytes and plasma cells between the follicles and by atrophy of the follicles. Lymphoid follicle formation with germinal centers is almost always present; the degree of atrophy and fibrosis of the follicles varies from mild to moderate.

Intrathyroidal lymphocyte subsets differ from those in blood. About 60% of infiltrating lymphoid cells are T cells, and about 30% express B-cell markers; the T-cell population is represented by helper ($CD4^+$) and cytotoxic ($CD8^+$) cells. The participation of cellular events in the pathogenesis is clear. Certain HLA haplotypes (HLA-DR4, HLA-DR5) are associated with an increased risk of goiter and thyroiditis, and others (HLA-DR3) are associated with the atrophic variant of thyroiditis.

A variety of different thyroid antigen autoantibodies are also involved. Thyroid antiperoxidase antibodies (TPOAbs), formerly called “antimicrosomal antibodies,” are demonstrable in the sera of 90% of children with lymphocytic thyroiditis and in many patients with Graves disease. TPOAbs inhibit enzyme activity and stimulate natural killer cell cytotoxicity. Antithyroglobulin antibodies occur in a smaller percentage of affected children but are much more common in adults. Thyrotropin receptor-blocking antibodies are frequently present, especially in patients with hypothyroidism, and it is now believed that they are related to the development of hypothyroidism and thyroid atrophy in patients with autoimmune thyroiditis.

Clinical Manifestations.

The disorder is four to seven times more frequent in girls than in boys. It may occur during the first 3 yr of life but becomes sharply more common after 6 yr of age and reaches a peak incidence during adolescence. The most common clinical manifestations are goiter and growth retardation. The goiter may appear insidiously and may be small or large. In most patients, the thyroid is diffusely enlarged, firm, and nontender. In about one third of patients, the gland is lobular and may seem to be nodular. Most of the affected children are clinically euthyroid and asymptomatic; some may have symptoms of pressure in the neck. Some children have clinical signs of hypothyroidism, but others who appear clinically euthyroid have laboratory evidence of hypothyroidism. A few children have manifestations suggestive of hyperthyroidism, such as nervousness, irritability, increased sweating, or hyperactivity, but results of laboratory studies are not necessarily those of hyperthyroidism. Occasionally, the disorder may coexist with Graves disease. Ophthalmopathy may occur in lymphocytic thyroiditis in the absence of Graves disease.

The clinical course is variable. The goiter may become smaller or may disappear spontaneously, or it may persist unchanged for years while the patient remains euthyroid. Most children who

are euthyroid at presentation remain euthyroid, although a percentage of patients acquire hypothyroidism gradually within months or years. Over several years, about half of children with subclinical hypothyroidism revert to euthyroidism, while the other half develop overt hypothyroidism. Thyroiditis is the cause of most cases of nongoitrous (atrophic) hypothyroidism.

Familial clusters of lymphocytic thyroiditis are common; the incidence in siblings or parents of affected children may be as high as 25%. Autoantibodies to thyroglobulin and human thyroid peroxidase in these families appear to be inherited in an autosomal dominant fashion, with reduced penetrance in males. The concurrence within families of patients with lymphocytic thyroiditis, “idiopathic” hypothyroidism, and Graves disease provides cogent evidence for a basic relationship among these three conditions. The disorder has been associated with many of the other autoimmune disorders. Autoimmune thyroiditis occurs in 10% of patients with *type I polyglandular autoimmune syndrome,* which consists of hypoparathyroidism, Addison disease, and mucocutaneous candidiasis (“HAM” syndrome). The association of Addison disease with insulin-dependent diabetes mellitus or autoimmune thyroid disease, or both, is known as *Schmidt syndrome* or *type II polyglandular autoimmune disease*. Autoimmune thyroid disease also tends to be associated with pernicious anemia, vitiligo, or alopecia. TPOAbs are found in approximately 20% of white and 4% of black children with diabetes mellitus. Autoimmune thyroid disease has an increased incidence in children with congenital rubella. Lymphocytic thyroiditis is also associated with certain chromosomal disorders, particularly Turner syndrome and Down syndrome. In children with Down syndrome, one study reported that 28% had antithyroid antibodies (predominantly anti-TPOs), 7% had subclinical hypothyroidism, 7% had overt hypothyroidism, and 5% had hyperthyroidism. In a study of girls with Turner syndrome, 41% had antithyroid antibodies (again, predominantly anti-TPOs), 18% had goiter, and 8% had subclinical or overt hypothyroidism. Another study of 75 girls with Turner syndrome found that autoimmune thyroid disease increased from the first (15%) to the third (30%) decade of life. Boys with Klinefelter syndrome are also at risk for autoimmune

thyroid disease.

Laboratory Findings.

The definitive diagnosis can be established by biopsy of the thyroid, but this procedure is rarely indicated for clinical purposes alone. Thyroid function tests are often normal, although the level of thyroid-stimulating hormone (TSH) may be slightly or even moderately elevated in some individuals, termed *subclinical hypothyroidism.* The fact that many children with lymphocytic thyroiditis do not have elevated levels of TSH indicates that the goiter may be caused by the lymphocytic infiltrations or by thyroid growth-stimulating immunoglobulins. In 50% of children, thyroid scans reveal irregular and patchy distribution of the radioisotope, and in about 60% or more, the administration of perchlorate results in a greater than 10% discharge of iodide from the thyroid gland. Thyroid ultrasonography shows scattered hypoechogenicity in most patients. Most patients with lymphocytic thyroiditis have serum antibody titers to TPO, but the antithyroglobulin test for thyroid antibodies is positive in fewer than 50%. When both tests are used, approximately 95% of patients with thyroid autoimmunity are detected. In general, levels in children and adolescents are lower than those in adults with lymphocytic thyroiditis, and repeated measurements are indicated in questionable instances because titers may increase later in the course of the disease.

Antithyroid antibodies may also be found in almost half the siblings of affected patients and in a significant percentage of the mothers of children with Down syndrome or Turner syndrome without demonstrable thyroid disease. They are also found in 20% of children with diabetes mellitus and in 23% of children with the congenital rubella syndrome.

Treatment.

If there is evidence of hypothyroidism, replacement treatment with sodium-L-thyroxine (50–150?µg daily) is indicated. The goiter usually shows some decrease in size but may persist for years. Antibody levels fluctuate in both treated and untreated patients and persist for years. Because the disease may be self-limited in some instances, the need for continued therapy requires periodic re-evaluation. Untreated patients should also be checked periodically. Prominent nodules that persist despite suppressive therapy should be examined histologically because thyroid cancer has occurred in patients with lymphocytic thyroiditis.

OTHER CAUSES OF THYROIDITIS

Specific conditions such as tuberculosis, sarcoidosis, mumps, and cat-scratch disease are rare causes of thyroiditis.

Acute suppurative thyroiditis is uncommon; it is usually preceded by a respiratory infection. The left lower lobe is affected predominantly. Abscess formation may occur. Anaerobic organisms, with or without aerobes, are the most common organisms; *Eikenella corrodens* has been reported. Recurrent episodes or the detection of a mixed bacterial flora suggests that the infection arises from a thyroglossal duct remnant or, more often, from a piriform sinus fistula. Exquisite tenderness of the gland, swelling, erythema, dysphagia, and limitation of head motion are characteristic findings. Systemic manifestations are often absent, and leukocytosis is present. Scintigrams of the thyroid often reveal decreased uptake in the affected areas, and ultrasonography may show a complex echogenic mass. Thyroid function is usually normal, but thyrotoxicosis due to escape of thyroid hormone has been encountered in a child with suppurative thyroiditis resulting from *Aspergillus.* When suppuration occurs, incision and drainage and administration of antibiotics are indicated. After the infection subsides, a barium esophagram is indicated to search for a fistulous tract; if one is found, exteriorization is indicated.

Subacute nonsupprative thyroiditis (de Quervain disease) is rare in children. It is thought to have a viral cause and remits spontaneously. The disorder becomes manifested by a vague tenderness over the thyroid and low-grade fever or by severe pain in the region of the thyroid and systemic manifestations with chills and high fever. Inflammation results in leakage of preformed thyroid hormone from the gland into the circulation. Serum levels of T_4 and T_3 are elevated, and mild symptoms of hyperthyroidism may be present, but radioiodine uptake is depressed. The erythrocyte sedimentation rate is increased. The course is variable, usually passing through a euthyroid to a hypothyroid phase; remission usually occurs in several months. Occasionally, this condition is superimposed on lymphocytic thyroiditis.

Chapter 561 - Goiter

A goiter is an enlargement of the thyroid gland. Persons with enlarged thyroids may have normal function of the gland *(euthyroidism)*, thyroid deficiency *(hypothyroidism)*, or overproduction of the hormones *(hyperthyroidism)*. Goiter may be congenital or acquired, endemic or sporadic.

The goiter often results from increased pituitary secretion of thyrotropic hormone in response to decreased circulating levels of thyroid hormones. Thyroid enlargement may also result from infiltrative processes that may be inflammatory or neoplastic. Goiter in patients with thyrotoxicosis is caused by thyrotropin receptor-stimulating antibodies.

Figure 561-1 Congenital goiter in infancy. *A,* Large congenital goiter in an infant born to a mother with thyrotoxicosis who had been treated with iodides and methimazole during pregnancy. *B,* A 6-wk-old infant with increasing respiratory distress and cervical mass since birth. The operation revealed a large goiter that almost completely encircled the trachea. Notice the anterior deviation and posterior compression of the trachea. Partial thyroidectomy completely relieved the symptoms. It is apparent why a tracheostomy is not adequate treatment for these infants. The cause for the goiter was not found.

561.1 Congenital Goiter

Congenital goiter is usually sporadic and may result from a fetal *thyroxine (T_4) synthetic defect* or the administration of *antithyroid drugs* or *iodides* during pregnancy for the treatment of thyrotoxicosis. Goitrogenic drugs and iodides cross the placenta and at high doses may interfere with synthesis of thyroid hormone, resulting in goiter and hypothyroidism in the fetus. The concomitant administration of thyroid hormone with the goitrogen does not prevent this effect, because insufficient amounts of T_4 cross the placenta. Iodides are included in many proprietary preparations used to treat asthma; these preparations must be avoided during pregnancy because they have often been a cause of unexpected congenital goiter. Amiodarone, an antiarrhythmic drug with a 37% iodine content, has also caused congenital goiter with hypothyroidism. Even when the infant is clinically euthyroid, there may be retardation of osseous maturation, low levels of T_4, and elevated levels of thyroid-stimulating hormone (TSH). In women with Graves disease on antithyroid drugs, these effects can occur when the mother takes only 100–200?mg of propylthiouracil/24?hr; all such infants should undergo thyroid studies at birth. Administration of thyroid hormone to affected infants may be indicated to treat clinical hypothyroidism, to hasten the disappearance of the goiter, and to prevent brain damage. Because the condition is rarely permanent, thyroid hormone may be

safely discontinued after the antithyroid drug has been excreted by the neonate, usually after a week.

Enlargement of the thyroid at birth may occasionally be sufficient to cause respiratory distress that interferes with nursing and may even cause death. The head may be maintained in extreme hyperextension. When respiratory obstruction is severe, partial thyroidectomy rather than tracheostomy is indicated (Fig. 561–1).

Goiter is almost always present in the *congenitally hyperthyroid* infant. These goiters usually are not large; the infant manifests

---

clinical symptoms of hyperthyroidism, and the mother often has a history of Graves disease (see Chapter 562.1). TSH receptor-activating mutations are also a recognized cause of congenital goiter.

When no causative factor is identifiable, a *defect in synthesis of thyroid hormone* should be suspected. Neonatal screening programs find congenital hypothyroidism caused by such a defect in 1/30,000–50,000 live births. If the infant is hypothyroid, it is advisable to treat immediately with thyroid hormone and to postpone more detailed studies for later in life. Because these defects are transmitted by recessive genes, a precise diagnosis is helpful for genetic counseling. Monitoring subsequent pregnancies with ultrasonography can be useful in detecting fetal goiters (see Chapters 85.2).

Iodine deficiency as a cause of congenital goiters is rare in developed countries, but persists in isolated endemic areas (see below). More important is the recent recognition that severe iodine deficiency early in pregnancy may cause neurologic damage during fetal development, even in the absence of goiter. The iodine deficiency may result in maternal and fetal hypothyroidism, preventing the partially protective transfer of maternal thyroid hormones.

When the “goiter” is lobulated, asymmetric, firm, or large to an unusual degree, a *teratoma* within or in the vicinity of the thyroid must be considered in the differential diagnosis (see Chapter 563).

561.2 Endemic Goiter and Cretinism

Etiology

IODINE DEFICIENCY.

The association between dietary deficiency of iodine and the prevalence of goiter or cretinism has been recognized for more than half a century. A moderate deficiency of iodine can be overcome by increased efficiency in the synthesis of thyroid hormone. Iodine liberated in the tissues is returned rapidly to the gland, which resynthesizes triiodothyronine (T_3) preferentially at a higher rate than normal. This increased activity is achieved by compensatory hypertrophy and hyperplasia, which satisfy the demands of the tissues for thyroid hormone. In geographic areas where deficiency of iodine is severe, decompensation and hypothyroidism may result. It is estimated that 2 billion individuals in developing countries live in areas of iodine deficiency.

Seawater is rich in iodine, and the iodine content of fish and shellfish is also high. Endemic goiter is rare therefore in populations living along the sea. Iodine is deficient in the water and native foods in the Pacific West and the Great Lakes areas of the United States. Deficiency of dietary iodine is even greater in certain Alpine valleys, the Himalayas, the Andes, the Congo, and the highlands of Papua New Guinea. In areas such as the United States, where iodine is provided in foods from other areas and in iodized salt, endemic goiter has disappeared. Iodized salt in the United States contains potassium iodide (100?µg/g) and provides excellent prophylaxis. Further iodine intake in the United States is contributed by iodates used in baking, iodine-containing coloring agents, and iodine-containing disinfectants used in the dairy industry. The recommended daily allowance of iodine for infants is greater than 30?µg/kg/24?hr; this amount is exceeded fourfold in breast-fed infants and 10-fold in infants fed cow's milk in the United States.

Clinical Manifestations.

If the deficiency of iodine is mild, thyroid enlargement does not become noticeable except when there is increased demand for the hormone during periods of rapid growth, as in adolescence and during pregnancy. In regions of moderate iodine deficiency, goiter observed in schoolchildren may disappear with maturity and reappear during pregnancy or lactation. Iodine-deficient goiters are more common in girls than in boys. In areas where iodine deficiency is severe, as in the hyperendemic highlands of Papua New Guinea, nearly half the population has large goiters, and endemic cretinism is common.

Serum T_4 levels are often low in individuals with endemic goiter, although clinical hypothyroidism is rare. This is true in New Guinea, the Congo, the Himalayas, and South America. Despite low serum levels of thyroid hormone, serum TSH concentrations are often only moderately increased. In such patients, circulating levels of T_3 are elevated. Moreover, T_3 levels are also elevated in patients with normal T_4 levels, indicating a preferential secretion of T_3 by the thyroid in this disease.

Endemic cretinism is the most serious consequence of iodine deficiency; it occurs only in geographic association with endemic goiter. The term *endemic cretinism* includes two different but overlapping syndromes—a neurologic type and a myxedematous type. The frequency of the two types varies among different populations. In Papua New Guinea, the neurologic type occurs almost exclusively, but in Zaire, the myxedematous type predominates. Both types are found in all endemic areas, and some individuals have intermediate or mixed features.

The neurologic syndrome is characterized by mental retardation, deaf-mutism, disturbances in standing and gait, and pyramidal signs such as clonus of the foot, the Babinski sign, and patellar hyperreflexia. Affected individuals are goitrous but euthyroid, have normal pubertal development and adult stature, and have little or no impaired thyroid function. Individuals with the myxedematous syndrome also are

mentally retarded and deaf and have neurologic symptoms, delayed sexual development and growth, myxedema, and absence of goiter; serum T_4 levels are low, and TSH levels are markedly elevated. Delayed skeletal maturation may extend into the 3rd decade or later. Ultrasonographic examination shows thyroid atrophy.

Pathogenesis.

The pathogenesis of the neurologic syndrome has been attributed to iodine deficiency and hypothyroxinemia during pregnancy, leading to fetal and postnatal hypothyroidism. Although some investigators have attributed brain damage to a direct effect of elemental iodine deficiency in the fetus, most believe the neurologic symptoms are caused by fetal and maternal hypothyroxinemia. There is evidence that the human fetal brain has receptors for thyroid hormone before development of the fetal thyroid, and there is also evidence of transplacental passage of maternal thyroid hormone into the fetus, which normally might ameliorate the effects of fetal hypothyroidism on the developing nervous system. The pathogenesis of the myxedematous syndrome leading to thyroid atrophy is more bewildering. Searches for additional environmental factors that may provoke continuing postnatal hypothyroidism have led to incrimination of selenium deficiency, goitrogenic foods, thiocyanates, and *Yersinia*. Studies from Western China suggest that thyroid autoimmunity may play a role. Myxedematous cretins with thyroid atrophy, but not euthyroid cretins, were found to have thyroid growth-blocking immunoglobulins of the kind found in infants with sporadic congenital hypothyroidism. Others are skeptical about any role of thyroid growth-blocking immunoglobulins to explain these findings.

Treatment.

In many developing countries, administration of a single intramuscular injection of iodinated poppy seed oil to women prevents iodine deficiency during future pregnancies for about 5 yr. This form of therapy given to children younger than 4 yr of age with myxedematous cretinism results in a euthyroid state in 5 mo. However, older children respond poorly and adults not at all to iodized oil injections, indicating an inability of the thyroid gland to synthesize hormone; these patients require treatment with T_4 . In the Xinjiang province of China, where the usual methods of iodine supplementation had failed, iodination of irrigation water has increased iodine levels in soil, animals, and human beings.

561.3 Sporadic Goiter

The term *sporadic goiter* encompasses goiters developing from a variety of causes; patients are usually euthyroid but may be hypothyroid. The most common cause of sporadic goiter is lymphocytic thyroiditis (see Chapter 560). Intrinsic biochemical defects in the synthesis of thyroid hormone are almost always associated with goiter. The occurrence of the disorder in siblings, onset in early life, and possible association with hypothyroidism (goitrous hypothyroidism) are important clues to the diagnosis.

Iodide Goiter.

A small percentage of patients treated with iodide preparations for prolonged periods acquire goiters. Iodides are commonly included for their expectorant effect in cough medicines and in proprietary mixtures for asthma. Goiters resulting from iodine administration are firm and diffusely enlarged, and in some instances hypothyroidism may develop. In normal individuals, acute administration of large doses of iodine inhibits the organification of iodine and the synthesis of thyroid hormone (Wolff-Chaikoff effect). This effect is short-lived and does not lead to hypothyroidism. When iodide administration continues, an autoregulatory mechanism in normal persons limits iodine trapping and permits the level of iodide in the thyroid to decrease and organification to proceed normally. In patients with iodide-induced goiter, this escape does not occur because of an underlying abnormality of biosynthesis of thyroid hormone. The persons most susceptible to the development of iodide goiter are those with lymphocytic thyroiditis or with a subclinical inborn error in thyroid hormone synthesis and those who have had a partial thyroidectomy.

Lithium carbonate also causes goiters; it is currently widely used as a psychotropic drug. Lithium competes with iodide; the mechanism producing the goiter or hypothyroidism is similar to that described earlier for iodide goiter. Lithium and iodide also act synergistically to produce goiter; their combined use should be avoided.

Amiodarone, a drug used to treat cardiac arrhythmias, can cause thyroid dysfunction with goiter because it is rich in iodine. It is also a potent inhibitor of 5'-deiodinase, preventing conversion of T_4 to T_3 . It can cause hypothyroidism, particularly in patients with underlying autoimmune disease; in other patients, it may cause hyperthyroidism.

Simple Goiter (Colloid Goiter).

A few children with euthyroid nontoxic goiters have simple goiters, a condition of unknown cause not associated with hypothyroidism or hyperthyroidism and not caused by inflammation or neoplasia. The condition predominates in girls and has a peak incidence before and during the pubertal years. Histologic examination of the thyroid either is normal or reveals variable follicular size, dense colloid, and flattened epithelium. The goiter may be small or large. It is firm in half the patients and is occasionally asymmetric or nodular. Levels of TSH are normal or low, scintiscans are normal, and thyroid antibodies are absent. Differentiation from lymphocytic thyroiditis may not be possible without a biopsy, but biopsy ordinarily is not indicated. Therapy with thyroid hormone may help avoid progression to a large multinodular goiter, although it is difficult to separate any treatment effects from the natural history, which is for the goiter to decrease in size. Untreated patients should be re-evaluated periodically. This condition must be differentiated from lymphocytic thyroiditis (see Chapter 560).

Multinodular Goiter.

Rarely, a firm goiter with a lobulated surface and single or multiple palpable nodules is encountered. Areas of cystic change, hemorrhage, and fibrosis may be present. The incidence of this condition has decreased markedly with the use of

iodine-enriched salt. A mild goitrogenic stimulus, acting over a long time, is thought to be the cause. Ultrasonographic examination may reveal multiple echo-free and echogenic lesions that are nonfunctioning on scintiscans. Thyroid studies are usually normal, but TSH may be elevated and thyroid antibodies may be present. The condition occurs in children with McCune-Albright syndrome (usually resulting in hyperthyroidism) and has been described in three children (including two siblings) with digital anomalies and cystic renal disease. Dominant nodules within a multinodular goiter, particularly those not suppressed by replacement therapy with T_4, may be an indication for evaluation by fine-needle aspiration because malignancy cannot readily be ruled out.

Toxic Goiter (Hyperthyroidism).

See Chapter 562 .

561.4 Intratracheal Goiter

One of the many ectopic locations of thyroid tissue is within the trachea. The intraluminal thyroid lies beneath the tracheal mucosa and is frequently continuous with the normally situated extratracheal thyroid. The thyroid tissue is susceptible to goitrous enlargement, which involves the normally situated and the ectopic thyroid. When there is obstruction of the airway associated with a goiter, it must be ascertained whether the obstruction is extratracheal or endotracheal. If obstructive manifestations are mild, administration of sodium-L-thyroxine usually causes the goiter to decrease in size. When symptoms are severe, surgical removal of the endotracheal goiter is indicated (also see Chapter 561.1).

Chapter 562 - Hyperthyroidism

Hyperthyroidism results from excessive secretion of thyroid hormone and, with few exceptions, is due to diffuse toxic goiter (Graves disease) during childhood. Germ line mutations of the thyroid-stimulating hormone (TSH) receptor resulting in constitutively activating (i.e., gain of function) mutations have been reported in both familial (autosomal dominant) and sporadic cases of non-autoimmune hyperthyroidism. These patients, who may present in the neonatal period or in later childhood, have thyroid hyperplasia with goiters and suppressed levels of TSH. Different activating mutations have been identified in some cases of thyroid adenomas. Hyperthyroidism occurs in some patients with McCune-Albright syndrome, which is the result of an activating mutation of the a subunit of the G protein; these patients tend to have a multinodular goiter. Other rare causes of hyperthyroidism that have been observed in children include toxic uninodular goiter (Plummer disease), hyperfunctioning thyroid carcinoma, thyrotoxicosis factitia, subacute thyroiditis, and acute suppurative thyroiditis. Suppression of plasma TSH indicates that the hyperthyroidism is not pituitary in origin. Hyperthyroidism due to excess thyrotropin secretion is rare and, in most cases, is caused by pituitary unresponsiveness to thyroid hormone. TSH-secreting pituitary tumors have been reported only in adults. In infants born to mothers with Graves disease, hyperthyroidism is almost always a transitory phenomenon; classic Graves disease during the neonatal period is rare. Choriocarcinoma, hydatidiform mole, and struma ovarii have caused hyperthyroidism in adults but have not been recognized as causes in children.

562.1 Graves Disease

Epidemiology.

Graves disease occurs in approximately 0.02% of children (1:5,000). It has a peak incidence in the 11–15 year old; there is a 5:1 female to male ratio. Most children with Graves disease have a positive family history of some form of autoimmune thyroid disease.

Etiology.

Enlargement of the thymus, splenomegaly, lymphadenopathy, infiltration of the thyroid gland and retro-orbital tissues with lymphocytes and plasma cells, and peripheral lymphocytosis are well-established findings in Graves disease. In the thyroid gland, T helper cells ($CD4^+$) tend to predominate in dense lymphoid aggregates; in areas of lower cell density, cytotoxic T cells ($CD8^+$) predominate. The

percentage of activated B lymphocytes infiltrating the thyroid is higher than in peripheral blood. A postulated failure of T suppressor cells allows expression of T helper cells, sensitized to the TSH antigen, which interact with B cells. These cells differentiate into plasma cells, which produce thyrotropin receptor-stimulating antibody (TRSAb). TRSAb binds to the receptor for TSH and stimulates cyclic adenosine monophosphate, analogous to TSH itself. In addition to TRSAb, thyrotropin receptor-blocking antibody (TRBAb) may also be produced, and the clinical course of the disease usually correlates with the ratio between the two antibodies.

The ophthalmopathy occurring in Graves disease appears to be caused by antibodies against antigens shared by the thyroid and eye muscle. TSH receptors have been identified in retro-orbital adipocytes and may represent a target for antibodies. The antibodies that bind to the extraocular muscles and orbital fibroblasts stimulate the synthesis of glycosaminoglycans by orbital fibroblasts and produce cytotoxic effects on muscle cells.

In whites, Graves disease is associated with HLA-B8 and HLA-DR3; the latter carries a sevenfold relative risk for Graves disease. Therefore, it is not surprising that Graves disease is also associated with other HLA-D3–related disorders such as Addison disease, insulin-dependent diabetes mellitus, myasthenia gravis, and celiac disease. Systemic lupus erythematosus, rheumatoid arthritis, vitiligo, idiopathic thrombocytopenic purpura, and pernicious anemia have been described in children with Graves disease. In family clusters, the conditions associated most frequently with Graves disease are lymphocytic thyroiditis, autoimmune hypothyroidism, and neonatal hyperthyroidism.

Clinical Manifestations.

About 5% of all patients with hyperthyroidism are younger than 15 yr of age; the peak incidence in these children occurs during adolescence. Graves disease has begun between 6 wk and 2 yr of age in children born to mothers without a history of hyperthyroidism. The incidence is about five times higher in girls than in boys.

The clinical course in children is highly variable but usually is not as fulminant as it is in many adults (Box 562–1). Symptoms develop gradually; the usual interval between onset and diagnosis is 6–12 mo and may be longer in prepubertal children compared with adolescents. The earliest signs in children may be emotional disturbances accompanied by motor hyperactivity. The children become irritable, excitable, and cry easily because of emotional lability. Their schoolwork suffers as a result of a short attention span. Tremor of the fingers can be noticed if the arm is extended. There may be a voracious appetite combined with loss of or no increase in weight. The size of the thyroid is variable. It may be enlarged so little that it escapes detection initially, but with careful examination, a goiter is found in almost all patients. Exophthalmos is noticeable in most patients but is usually mild. Lagging of the upper eyelid as the eye looks downward, impairment of convergence, and retraction of the upper eyelid and infrequent blinking may be present (Fig. 562–1). The skin is smooth and flushed, with excessive sweating. Muscular weakness is uncommon but may be severe enough to result in falling spells. Tachycardia, palpitations, dyspnea, and cardiac enlargement and insufficiency cause discomfort but rarely endanger the patient's life. Atrial fibrillation is a rare complication. Mitral regurgitation, probably resulting from papillary muscle dysfunction, is the cause of the apical systolic murmur present in some patients. The systolic blood pressure and the pulse pressure are increased. Many of the findings in Graves disease result from hyperactivity of the sympathetic nervous system.

Thyroid “crisis,” or “storm,” is a form of hyperthyroidism manifested by an acute onset, hyperthermia, and severe tachycardia and restlessness. There may be rapid progression to delirium, coma, and death. “Apathetic,” or “masked,” hyperthyroidism is another variety of hyperthyroidism characterized by extreme listlessness, apathy, and cachexia. A combination of both forms may also occur. These symptom complexes are rare in children.

Laboratory Findings.

Serum levels of thyroxine (T_4), triiodothyronine (T_3), free T_4 , and free T_3 are elevated. In some patients, levels of T_3 may be more elevated than those of T_4 . Levels of TSH are suppressed to less than normal levels. Thyroid peroxidase antibodies are often present. Most patients with newly diagnosed Graves disease have measurable TRSAb, and its disappearance predicts remission of the disease. Assays of TSH receptor antibodies are generally not necessary for diagnosis or management of Graves disease, but can be helpful in equivocal cases. Radioiodine is rapidly and diffusely concentrated in the thyroid, but this study is rarely necessary. Very young children

Box 562.1-1. Major Symptoms and Signs of Hyperthyroidism and of Graves Disease and Conditions Associated with Graves Disease

MANIFESTATIONS OF HYPERTHYROIDISM

Symptoms

- Hyperactivity, irritability, altered mood, insomnia
- Heat intolerance, increased sweating
- Palpitations
- Fatigue, weakness
- Dyspnea
- Weight loss with increased appetite (weight gain in 10% of patients)
- Pruritus
- Increased stool frequency
- Thirst and polyuria
- Oligomenorrhea or amenorrhea, loss of libido

Signs

- Sinus tachycardia, atrial fibrillation
- Fine tremor, hyperkinesis, hyperreflexia
- Warm, moist skin
- Palmar erythema, onycholysis
- Hair loss
- Muscle weakness and wasting
- High-output heart failure, chorea, periodic paralysis (primarily in Asian men), psychosis[*]

- Muscle weakness and wasting
- High-output heart failure, chorea, periodic paralysis (primarily in Asian men), psychosis[*]

MANIFESTATIONS OF GRAVES DISEASE

- Diffuse goiter
- Ophthalmopathy
  - A feeling of grittiness and discomfort in the eye
  - Retrobulbar pressure or pain
  - Eyelid lag or retraction
  - Periorbital edema, chemosis, scleral injection
  - Exophthalmos (proptosis)
  - Extraocular muscle dysfunction
  - Exposure keratitis
  - Optic neuropathy
- Localized dermopathy
- Lymphoid hyperplasia
- Thyroid acropachy

CONDITIONS ASSOCIATED WITH GRAVES DISEASE

- Type 1 diabetes mellitus
- Addison disease
- Vitiligo
- Pernicious anemia
- Alopecia areata
- Myasthenia gravis
- Celiac disease

Alopecia areata

Myasthenia gravis

Celiac disease

Other autoimmune disorders associated with the HLA-DR3 haplotype

Adapted from Weetman AP: Graves disease, N Engl J Med 2000;343: 1236–48.

*These signs are rare.

with Graves disease often have advanced skeletal maturation and craniostenosis. Bone density may be reduced at diagnosis but returns to normal with treatment.

Differential Diagnosis.

Diagnosis is rarely difficult once hyperthyroidism is considered. Elevated levels of T_4 and free T_4 in association with suppressed levels of TSH are usually diagnostic. The presence of TRSAb establishes the cause as Graves disease.

Most other causes of hyperthyroxinemia are rare but may result in erroneous diagnosis. Patients with elevated thyroxine-binding globulin (TBG) levels or familial dysalbuminemic hyperthyroxinemia have normal levels of free T_4 and TSH. If a thyroid nodule is palpable, or if T_3 is preferentially elevated, a functional thyroid nodule must be considered; radionuclide study is diagnostic. If precocious puberty, polyostotic fibrous dysplasia, or café-au-lait pigmentation is present, the autonomous thyroid disorder of McCune-Albright syndrome is likely. Patients with generalized thyroid hormone unresponsiveness have elevated levels of free T_4 , but levels of TSH are inappropriately elevated or normal. Patients with pituitary unresponsiveness to thyroid hormone also have clinical hyperthyroidism, but their levels of TSH are elevated

Figure 562.1-1 A 15-yr-old girl with classic Graves disease. Clinical features include a goiter and exophthalmos. She was treated with antithyroid drugs, to which she had a good response.

or normal, and they must be differentiated from patients with TSH-secreting pituitary tumors who have elevated serum levels of the TSH a chain.

When hyperthyroxinemia is caused by exogenous thyroid hormone, levels of free T_4 and TSH are the same as those seen in Graves disease, but the level of thyroglobulin is very low, whereas in patients with Graves disease, it is elevated.

Treatment.

Most pediatric endocrinologists recommend medical therapy using *antithyroid drugs* rather than radioiodine or subtotal thyroidectomy. The two antithyroid drugs in widest use are propylthiouracil (PTU) and methimazole (Tapazole). Both compounds inhibit incorporation of trapped inorganic iodide into organic compounds, and they may also suppress levels of TRSAb by directly affecting intrathyroidal autoimmunity. However, there are important differences between the two drugs. Methimazole is at least 10 times more potent than PTU on a weight basis and has a much longer serum half-life (6–8?hr vs 0.5?hr); PTU generally is administered three times daily, but methimazole can be given once daily. Unlike methimazole, PTU is heavily protein-bound and has a lesser ability to cross the placenta and to pass into breast milk; theoretically, PTU is the preferred drug during pregnancy and for nursing mothers. PTU, more than methimazole, inhibits extrathyroidal conversion of T_4 to T_3 ; this may be advantageous in the treatment of neonatal thyrotoxicosis.

Toxic reactions occur with both drugs; most are mild, but some are life-threatening. They are unpredictable and can occur after therapy of any duration. There is increasing evidence that these

reactions may be fewer in patients treated with methimazole. Transient leukopenia (<4,000/mm^3) is common; it is asymptomatic and is not a harbinger of agranulocytosis, and it usually is not a reason to discontinue treatment. Transient urticarial rashes are common. They can be managed by a short period off therapy, restarting with the alternate antithyroid drug. The most severe reactions are hypersensitive and include agranulocytosis, hepatitis, hepatic failure, a lupus-like syndrome, glomerulonephritis, and a vasculitis involving the skin and other organs. Although uncommon, these reactions have been reported with both drugs, and it is probably best to treat unusually hypersensitive patients with radioiodine or thyroidectomy. Cases of congenital skin defects (aplasia cutis) have been seen in infants exposed in fetal life to methimazole, but this association does not appear to be a strong one.

The initial dosage of PTU is 5–10?mg/kg/24?hr given three times daily, and that of methimazole is 0.25–1.0?mg/kg/24?hr given once or twice daily. Smaller initial dosages should be used in early childhood. Careful surveillance is required after treatment is initiated. Rising serum levels of TSH to greater than normal indicates overtreatment and leads to increased size of the goiter. Clinical response becomes apparent in 2–3 wk, and adequate control is evident in 1–3 mo. The dose is decreased to the minimal level required to maintain a euthyroid state.

Drug therapy may be necessary for 5 yr or longer because there appears to be a remission rate of about 25% every 2 yr. If a relapse occurs, it usually appears within 3 mo and almost always within 6 mo after therapy has been discontinued. Therapy may be resumed in case of a relapse. Patients older than 13 yr of age, boys, those with a higher body mass index, and those with small goiters and modestly elevated T_3 levels appear to have earlier remissions.

A ß-adrenergic blocking agent such as propranolol (0.5–2.0?mg/kg/24?hr po, given three times daily) is a useful supplement in the management of severely toxic patients. Thyroid hormones potentiate the actions of catecholamines, which include

tachycardia, tremor, excessive sweating, lid lag, and stare. These symptoms abate with the use of propranolol, which does not, however, alter thyroid function or exophthalmos.

Surgery or radioiodine treatment is indicated when adequate cooperation for medical management is not possible or when adequate trial of medical management has failed to result in permanent remission or severe side effects preclude further use of antithyroid drugs. Subtotal thyroidectomy, a rather safe procedure if performed by an experienced team, is performed only after the patient has been brought to a euthyroid state. This may be accomplished with PTU or methimazole over 2–3 mo. After a euthyroid state has been attained, 5 drops of a saturated solution of potassium iodide/24?hr are added to the regimen for 2 wk before surgery to decrease the vascularity of the gland. Complications of surgical treatment are rare and include hypoparathyroidism (transient or permanent) and paralysis of the vocal cords. The incidence of residual or recurrent hyperthyroidism or hypothyroidism depends on the extent of the surgery. Most recommend near-total thyroidectomy. The incidence of recurrence is low, but that of hypothyroidism may exceed 50%.

Radioiodine is an effective, relatively safe first or alternate therapy for Graves disease in children over 10yr old. Pretreatment with antithyroid drugs is unnecessary; if a patient is taking them, they should be stopped a week before radioiodine administration. Most children become euthyroid after one dose (88% in one study), but a few may require a second or third dose. Because the full effects of treatment may not be complete for 2–3 mo, adjunctive therapy with a ß-adrenergic antagonist and lower doses of antithyroid drugs are recommended. Although there have been concerns about radiation oncogenesis and genetic damage, follow-up of treated children for as long as 50 yr has not shown this. The risk of benign adenoma may be increased (0.6–1.9% in one study). The major consequence of radioiodine is hypothyroidism, which occurs in 10–20% of patients after the first year and in about 3% per year thereafter.

The ophthalmopathy remits gradually and usually independently of the hyperthyroidism. Severe ophthalmopathy may require treatment with prednisone or radiotherapy.

562.2 Congenital Hyperthyroidism

Etiology and Pathogenesis.

Onset of neonatal hyperthyroidism usually begins prenatally and is present at birth, although it may not be noticed until a few days after birth; occasionally, onset may be delayed for several weeks or more. The mothers of these infants have active Graves disease, Graves disease in remission or, rarely, hypothyroidism, and a history of lymphocytic thyroiditis. The condition is caused by transplacental passage of TRSAb, but the clinical onset, severity, and course may be modified by the concurrent presence of TRBAb and by the transplacental passage of antithyroid drugs taken by the mother. Very high levels of TRSAb usually result in classic neonatal hyperthyroidism, but if the infant has been exposed to the antithyroid drugs, onset of symptoms is delayed 3–4 days to allow degradation of the maternally derived antithyroid drug. If TRBAb is also present, onset of hyperthyroid symptoms may be delayed for several weeks.

Neonatal hyperthyroidism occurs in only about 2% of infants born to mothers with a history of Graves disease. The finding of very high levels of TRSAb in these mothers usually predicts the occurrence of an affected infant. Fetal tachycardia and goiter may allow prenatal diagnosis. Unlike Graves disease at all other ages, neonatal hyperthyroidism affects boys as often as girls. The disorder usually remits spontaneously within 6–12 wk but may persist longer, depending on the levels of TRSAb. Mild asymptomatic hyperthyroxinemia also occurs. Rarely, classic neonatal Graves' disease does not remit but persists for several years or longer. These children have impressive family histories of Graves' disease. In these infants, TRSAb transfer from the mother apparently blends with the infantile onset of autonomous Graves disease.

Clinical Manifestations.

Many of the infants are premature and appear to have intrauterine growth retardation. Most have goiters. The infant is extremely restless, irritable, and hyperactive, and appears anxious and unusually alert. Microcephaly and ventricular enlargement may be present. The eyes are opened widely and appear exophthalmic (Fig. 562–2). There may be extreme tachycardia and tachypnea, and the temperature is elevated. In severely affected infants, there is a progression of symptoms; weight loss occurs despite a ravenous appetite, hepatosplenomegaly increases, and jaundice may become manifested. Cardiac decompensation is common, and severe hypertension may occur. The infant may die if therapy is not instituted promptly. The serum level of T_4 is markedly elevated and TSH is suppressed. Advanced bone age, frontal bossing with triangular facies, and cranial synostosis are common, especially in infants with persistent clinical manifestations of hyperthyroidism.

Treatment.

Treatment consists of oral administration of propranolol (1–2?mg/kg/24?hr, orally in three divided doses) and PTU (5–10?mg/kg/24?hr given every 8?hr); Lugol solution (1 drop every 8?hr) may be added. When propranolol is used during pregnancy to treat thyrotoxicosis, it crosses the placenta and may cause respiratory depression in the newborn infant. If the thyrotoxic state is severe, parenteral fluid therapy and corticosteroids may be indicated. If heart failure occurs, digitalization is indicated. After a euthyroid state is reached, only PTU treatment is necessary. The dose should be gradually tapered to keep the infant euthyroid. Most cases remit by 3–4 mo of age.

Occasionally, neonatal hyperthyroidism does not remit but persists into childhood. These patients may have an impressive family history of hyperthyroidism. Several cases of neonatal

Figure 562.2-2 Twin boys with neonatal hyperthyroidism confirmed by abnormal thyroid function tests. Clinical features include lack of subcutaneous tissue due to a hypermetabolic state and a wide-eyed, anxious stare. They were given the diagnosis of neonatal Graves disease, but, in fact, their mother did not have Graves disease; they had persistent, not transient, hyperthyroidism. At age 8 yr, they were treated with radioiodine. They are now believed to have had some other form of neonatal hyperthyroidism, such as a constitutive activation of the TSH receptor.

hyperthyroidism, without evidence for autoimmune disease in infant or mother, have now been reported due to a mutation in the TSHR gene, which produced constitutive activation of the receptor. Hyperthyroidism recurs when antithyroid drugs are discontinued; these children must be treated with radioiodine or surgery.

Prognosis.

Advanced osseous maturation, microcephaly, and mental retardation occur when treatment is delayed. Prognosis for intellectual development is guarded in infants with neonatal Graves disease.

Chapter 563 - Carcinoma of the Thyroid

Epidemiology.

Carcinoma of the thyroid is rare in childhood; the annual incidence in children younger than 15 yr of age is approximately 0.5 cases/million, compared with an annual incidence at all ages around the world ranging from 0.5 to 10 cases/million. Unlike other malignancies in childhood, thyroid cancer usually has an indolent course, even after pulmonary metastases have developed.

Pathogenesis.

Genetic factors and radiation exposure are important factors in the pathogenesis of thyroid cancer. Rearrangements of the RET proto-oncogene are found in 3–33% of papillary carcinomas and 60–80% of those occurring after irradiation, as in children in Belarus exposed to radiation after the nuclear accident at Chernobyl or in those who were exposed to external radiation in childhood. Inactivating point mutations of the p53 tumor-suppressor gene are rare in patients with differentiated thyroid carcinoma but are common in those with anaplastic thyroid cancer. Overall, 5–10% of cases of papillary thyroid carcinoma are familial and are usually inherited in an autosomal dominant manner. The thyroid gland of children is unusually sensitive to exposure to external radiation. There probably is no threshold dose; 1?Gy results in a 7.7 relative risk of thyroid cancer. In the past, about 80% of children with cancer of the thyroid had received irradiation of the neck and adjacent areas during infancy for benign conditions such as “enlarged” thymus, hypertrophied tonsils and adenoids, hemangiomas, nevi, eczema, tinea capitis, and “cervical adenitis.” With the discontinuation of irradiation for benign conditions, this cause of thyroid cancer has vanished. However, the long-term survival of children who have received therapeutic irradiation of areas of the neck for neoplastic disease has now made this cause of thyroid cancer and nodules increasingly prevalent; increased dose,

younger age at time of treatment, and female sex are factors that increase the risk of thyroid cancer developing. Long-term risk data for cancer are sparse, but 15–50% of children who have received irradiation and chemotherapy for Hodgkin disease, leukemia, and other malignancies of the head and neck have elevated levels of thyroid-stimulating hormone (TSH) within the 1st yr of therapy, and 5–20% progress to hypothyroidism during the next 5–7 yr. Most large groups of treated children have a 10–30% incidence of benign thyroid nodules and an increased incidence of thyroid

cancer. The latter begins to appear within 3–5 yr after radiation treatment and reaches a peak in 15–25 yr. It is unknown whether there is a period after which no more tumors develop. Administration of iodine-131 for diagnostic or therapeutic purposes does not appear to increase the risk of thyroid cancer.

Histologically, the carcinomas are papillary (80%), follicular (17%), medullary (2%), or mixed differentiated tumors. These are usually slow-growing tumors and may remain dormant for years. The type of tumor and the natural course of disease in irradiated and nonirradiated patients are the same, except that multicentricity is more frequent in irradiation-induced cancer. Undifferentiated (anaplastic) thyroid neoplasms are rare in children and usually have a rapidly fatal course.

Clinical Manifestations.

Girls are affected twice as often as boys. The average age at diagnosis is 9 yr, but the onset may be as early as the 1st yr of life. A painless nodule in the thyroid or in the neck is the usual first evidence of disease. Cervical lymph node involvement is often present at the time of initial diagnosis. Any unexplained cervical lymph node enlargement requires examination of the thyroid, which occasionally has a primary tumor too small to be felt; the diagnosis is based on biopsy results of the lymph node. The lungs are the most common site of metastases beyond the neck. There may be no clinical manifestations referable to them; roentgenographically, they appear as diffuse miliary or nodular infiltrations, principally in the basal portions. They may be mistaken for tuberculosis, histoplasmosis, or sarcoidosis. Other sites of metastases include the mediastinum, long bones, skull, and axilla. Almost all children are euthyroid, but rarely, the carcinoma may be functional and produce symptoms of hyperthyroidism.

Diagnosis.

The most helpful diagnostic test in the case of a solitary nodule is fine needle aspiration (FNA). An ultrasonographic examination of the thyroid can provide information on the consistency of the nodule (solid vs cystic) and whether other nonpalpable nodules are present. A thyroid scan, preferably using ^{123}I or ^{99m}Tc-pertechnetate, can provide information on trapping function, and whether the nodule is “cold,” “warm,” or “hot.” The majority of cold nodules are benign. Neither ultrasound nor a thyroid scan can differentiate between a benign or malignant lesion. FNAs may be interpreted as benign tumor, malignant tumor, indeterminate, or inadequate specimen. Experience in children using FNA generally shows a 5–10% false-negative rate and a 1–2% false-positive rate, with an overall diagnostic accuracy of 90–95%. Generally tests of thyroid function are normal, but Hashimoto's thyroiditis has been associated with thyroid cancer.

Treatment.

Because differentiated thyroid carcinoma is a chronic disease with a long survival, optimal therapy is still evolving. There is increasing evidence that small (<1?cm) papillary carcinoma, the least aggressive type, is effectively treated by subtotal thyroidectomy and suppressive doses of thyroid hormone. Papillary carcinomas tend to be multicentric, and several studies show that half these children have regional lymph node involvement at presentation. For larger papillary carcinomas, follicular carcinoma, or with regional lymph node involvement, near-total thyroidectomy with excision of regional lymph nodes appears to be the treatment of choice. There is no role for radical neck dissection. Thyroidectomy is usually followed by an ablative dose (30–100?mCi) of ^{131}I.

After surgery, all patients should be treated with sodium-L-thyroxine in doses sufficient to suppress TSH to the lower range of normal. Serum thyroglobulin (Tg) is an excellent marker for tumor recurrence, and periodic determinations of Tg levels should be performed. If the patient has undergone a total thyroidectomy or ^{131}I ablation, the serum Tg level should be less than 5?ng/mL when thyroxine (T_4) suppressive therapy is being received. Patients with an elevated serum Tg should undergo radioactive iodine uptake and scan to locate the source of Tg and plan appropriate management.

Prognosis.

For any form of therapy, survival or recurrence does not appear to be different for patients with or without involvement of the cervical nodes. Even patients with cervical or pulmonary metastases have survived many years. More than 95% of patients are alive 25 yr after initial treatment if the tumor was intrathyroid, less than 2?cm in diameter, and classified as grade 1. Greater tumor size, distant spread, and greater atypia are associated with increased cumulative mortality.

563.1 Solitary Thyroid Nodule

Solitary nodules of the thyroid are uncommon in children. Most are the result of benign tumors, such as follicular adenoma. In the past, it was estimated that as many as half were carcinomas, but later studies indicated that there is an approximately 15% incidence of malignancy, perhaps because of decreasing exposure of children to radiation (Box 563–1). Children exposed to radiation have a high incidence of benign adenoma and carcinoma of the thyroid.

Benign disorders that may present as solitary thyroid nodules include benign adenomas (e.g., follicular, embryonal, Hürthle cell), colloid (adenomatous) nodule, lymphocytic thyroiditis, thyroglossal duct cyst, ectopically located normal thyroid tissue, a single median thyroid, agenesis of one of the lateral thyroid lobes with hypertrophy of the contralateral lobe, thyroid cysts, and abscess. A suddenly appearing or rapidly enlarging thyroid mass may indicate hemorrhage into a benign adenoma. In most cases, the child is euthyroid, and thyroid function studies are normal. When lymphocytic thyroiditis is the cause of the nodule, T_4 may be low, TSH may be elevated, and thyroid antibodies are usually present. Radionuclide imaging, if performed, may reveal a moth-eaten appearance. Rarely, lymphocytic thyroiditis may be associated with carcinoma of

Box 563.1-1. Etiologic Classification of Solitary Thyroid Nodules

- Lymphoid follicle, as part of chronic lymphocytic thyroiditis
- Thyroid developmental anomalies
  - Hemiagenesis
  - Intrathyroidal thyroglossal duct cyst
- Thyroid abscess (acute suppurative thyroiditis)
- Simple cyst
- Neoplasms
  - Benign
    - Colloid (adenomatous) nodule
    - Follicular adenoma
    - Toxic adenoma
    - Nonthyroidal (e.g., lymphohemangioma)
  - Malignant
    - Papillary carcinoma
    - Follicular carcinoma
    - Mixed papillary-follicular carcinoma
    - Undifferentiated (anaplastic)
    - Medullary carcinoma
    - Nonthyroidal
      - Lymphoma
      - Teratoma

the thyroid. Ultrasonography is particularly useful in detecting cystic lesions.

The *diagnostic studies* to delineate the underlying cause include serum thyroid function tests, antithyroid antibody determinations, ultrasonographic examination of the thyroid, radionuclide uptake and scan, and FNA. Response to a trial of suppressive T_4 treatment to look for shrinkage of nodule size is not reliable. Although *thyroid carcinomas* generally present as a solid, cold nodule, most cold nodules are benign lesions. FNA is useful in avoiding surgery for benign nodules. However, surgery without delay is indicated when the nodule is hard or has grown rapidly, when there is evidence of tracheal or vocal cord involvement, or when there is enlargement of adjacent lymph nodes. All persons with a history of head or neck irradiation should have careful examinations of the thyroid at least every 2 yr indefinitely.

Rarely, thyroid nodules may be functional, producing hyperthyroidism *(Plummer disease).* The uptake of radionuclide is concentrated in the nodule (“hot” or “warm” nodule), and thyroid function studies indicate that the nodule is functioning autonomously. Such nodules are usually benign, but a few instances of carcinoma in such cases have been reported. T_4 levels are usually normal, but triiodothyronine (T_3) levels are elevated (T_3 toxicosis), and TSH levels are suppressed. Treatment consists of surgical removal of the nodule.

563.2 Medullary Carcinoma

Medullary carcinoma of the thyroid arises from the parafollicular cells (C cells) of the thyroid and accounts for about 2% of thyroid malignancies. The most common symptom is goiter or a palpable thyroid nodule. Roentgenograms may reveal dense, conglomerate, homogeneous calcification in the thyroid. Metastases to the regional lymph nodes and to the liver are common, and these also may calcify. Death may result, but long survivals are common.

The tumors occur sporadically, as a familial autosomal dominant disorder, and as components of two distinct autosomal dominant syndromes. The susceptibility for all these disorders has been associated with germ line mutations of the RET proto-oncogene, which maps to chromosome 10q11.2. When the tumor occurs sporadically, it is usually unicentric, but in the familial form, it is usually multicentric, and it begins as hyperplasia of parafollicular cells. The tumors are often too small to be found by palpation, scintigraphy, or ultrasonographic examination in at-risk patients in these families. Diagnosis of medullary carcinoma should lead to a careful search for associated tumors, particularly pheochromocytoma. No clinically recognizable manifestations result from the elevated serum levels of calcitonin or from the calcitonin gene-related peptide.

Multiple Endocrine Neoplasia, Type IIA.

When hyperplasia or carcinoma of C cells is associated with adrenal medullary

hyperplasia or pheochromocytoma and parathyroid hyperplasia, it is known as multiple endocrine neoplasia (MEN) IIA. The inheritance pattern for MEN IIA is autosomal dominant, with a high degree of penetrance and variable expressivity. At least 19 different specific missense mutations of exon 10 or 11 of the extracellular domain of the RET gene have been described for MEN IIA and for cases of familial medullary thyroid carcinoma. DNA analysis permits unambiguous identification of carriers of the RET proto-oncogene gene. C-cell hyperplasia or tumors usually appear earlier than pheochromocytoma. Pheochromocytomas are frequently bilateral and may be multiple. Adrenal medullary hyperplasia is known to precede pheochromocytoma, but the detectable latent period is short. Hypercalcemia is a late manifestation and indicates hyperparathyroidism. The parathyroid glands may reveal chief-cell hyperplasia or only hypercellularity.

Multiple Endocrine Neoplasia, Type IIB.

The distinguishing feature of MEN IIB, also called the *mucosal neuroma syndrome,* is the occurrence of multiple neuromas and a characteristic phenotype associated with medullary carcinoma and pheochromocytoma. This condition is also autosomal dominant, and 93% of families have a missense mutation of the RET proto-oncogene. However, the mutation is in exon 16, the tyrosine catalytic domain of RET; all patients have had the same point mutation.

The neuromas most often occur on the tongue, buccal mucosa, lips, and conjunctivae. Peripheral neurofibromas and café-au-lait patches may be present, and intestinal ganglioneuromatosis is common. Diffuse proliferation of nerves and ganglion cells is found in mucosal, submucosal, myenteric, and subserosal plexus involving the small and large bowel as well as the esophagus. The patients may be tall, with arachnodactyly and a Marfan-like appearance. Scoliosis, pectus excavatum, pes cavus, and muscular hypotonia are common. The eyelids may be thickened and everted, the lips patulous and blubbery, the jaw prognathic. Feeding difficulties, poor sucking, diarrhea, constipation, and failure to thrive may begin in infancy or early childhood, many years before the appearance of neuromas or endocrine symptoms.

Treatment.

Total thyroidectomy is indicated for all children who are shown by DNA studies to carry the gene. Recognition of familial forms of this tumor is critical to the early diagnosis in children at risk. Evidence suggests that thyroidectomy must be performed early because medullary carcinoma has been seen in a 6-mo-old child with MEN IIB and in a 3-yr-old child with MEN IIA. Monitoring the levels of calcitonin is useful in following the course of the disease after operation and detecting metastatic lesions. Periodic screening for the development of pheochromocytoma is indicated.

Section 3 - *Disorders of the Parathyroid*

Daniel A. Doyle
Angelo M. DiGeorge

Chapter 564 - Hormones and Peptides of Calcium Homeostasis and Bone Metabolism

Parathyroid hormone (PTH) and vitamin D are the principal regulators of calcium homeostasis (see Chapters 44 , 48 , and 691). Calcitonin and PTH-related peptide (PTHrP) appear to be important primarily in the fetus.

Parathyroid Hormone.

PTH is an 84-amino acid chain (9,500 d), but its biologic activity resides in the first 34 residues. In the parathyroid gland, a pre-pro-PTH (115-amino acid chain) and a proparathyroid hormone (90 amino acids) are synthesized. Pre-pro-PTH is converted to pro-PTH and pro-PTH to PTH. PTH (1–84) is the major secretory product of the gland, but it is rapidly cleaved in the liver and kidney into smaller COOH-terminal, mid-region, and NH_2 -terminal fragments.

The occurrence of these fragments in serum has led to the development of a variety of assays. The 1–34 amino-terminal (N-terminus) fragments possess biologic activity but are present in low amounts in the circulation; assay of these fragments is most useful for detecting acute secretory changes. The carboxy-terminal (C-terminus) and mid-region fragments, although biologically inert, are cleared more slowly from the circulation and represent 80% of plasma immunoreactive PTH; values of the C-terminal fragment are 50–500 times the level of the active hormone. The C-terminal assays are effective in detecting patients with hyperparathyroidism, but because C-terminal fragments are removed from the circulation by glomerular filtration, these assays are less useful for evaluating the secondary hyperparathyroidism characteristic of renal disease. Only certain sensitive radioimmunoassays for PTH can differentiate the subnormal concentrations that occur in hypoparathyroidism from normal levels. A sensitive 15-min immunochemiluminometric assay, developed for intraoperative use, can provide the surgeon with useful information.

When serum levels of calcium fall, the signal is transduced through the calcium-sensing receptor and secretion of PTH increases (Fig. 564–1). PTH stimulates activity of 1a-hydroxylase in the kidney, enhancing production of 1,25-dihydroxycholecalciferol (1,25[OH]$_2$ D$_3$). The increased level of 1,25[OH]$_2$ D$_3$ induces synthesis of a calcium-binding protein *(calbindin-D)* in the intestinal mucosa with resultant absorption of calcium. PTH also mobilizes calcium by directly enhancing bone resorption, an effect that requires 1,25[OH]$_2$ D$_3$. The effects of PTH on bone and kidney are mediated through binding to specific receptors on the membranes of target cells and through activation of a transduction pathway involving a G protein coupled to the adenylate cyclase system (also see Chapter 566).

The *calcium-sensing receptor* regulates the secretion of PTH and the reabsorption of calcium by the renal tubules in response to alterations in serum calcium concentrations. The gene for the receptor is located on chromosome 3q13.3-q21 and encodes a cell surface protein of 1,078 amino acids that is expressed in parathyroid glands and kidneys and belongs to the family of G protein–coupled receptors. In the normally functioning calcium-sensing receptor, hypocalcemia induces increased secretion of PTH and hypercalcemia depresses PTH secretion. Loss of function mutations result in an increased set point with respect to serum calcium, resulting in hypercalcemia and in the conditions of familial hypocalciuric hypercalcemia and neonatal severe hyperparathyroidism. Gain of function mutations result in depressed secretion of PTH in response to hypocalcemia, leading to the syndrome of familial hypocalcemia with hypercalciuria (see Fig. 564–1).

Parathyroid Hormone-Related Peptide.

PTHrP is homologous to PTH only in the first 13 amino acids of its amino terminus, 8 of which are identical to PTH. Its gene is on the short arm of chromosome 12, and that of PTH is on the short arm of chromosome 11.

PTHrP, like PTH, activates PTH receptors in kidney and bone cells and increases urinary cyclic adenosine monophosphate and renal production of 1,25[OH]$_2$ D$_3$. It is produced in almost every type of cell of the body, including every tissue of the embryo at some stage of development. PTHrP is critical for normal fetal development. Inactivating mutations of the receptor for PTH/PTHrP result in a lethal bone disorder characterized by short limbs and markedly advanced bone maturation known as *Blomstrand chondrodysplasia* (see Fig. 564–1). It appears to have a paracrine or autocrine role because serum levels are low except in a few clinical situations. Cord blood contains levels of PTHrP that are threefold higher than in serum from adults; it is produced by the fetal parathyroid glands and appears to be the main agent stimulating maternal-fetal calcium transfer. PTHrP appears to be essential for normal skeletal maturation of the fetus, which requires 30?g of calcium. During pregnancy, maternal absorption of calcium increases from about 150?mg daily to 400?mg during the second trimester.

As in cord blood, PTHrP levels are increased during lactation and in patients with benign breast hypertrophy. Breast milk and pasteurized bovine milk have levels of PTHrP that are 10,000 times higher than those of normal plasma. Most instances of the hormonal hypercalcemia syndrome of malignancy are caused by elevated concentrations of PTHrP.

Vitamin D.

See Chapters 44 and 48 .

Figure 564-1 Some components involved in calcium homeostasis. (From Thakker RV: Genetic development in hypoparathyroidism. *Lancet* 2001;357:974–76, with permission.)

Calcitonin.

Calcitonin (CT) is a 32-amino acid polypeptide. Its gene is on chromosome 11p and is tightly linked to that of PTH. The gene for CT encodes three peptides: CT, a 21-amino acid carboxy-terminal flanking peptide (katacalcin), and a CT gene-related peptide. Katacalcin and CT are co-secreted in equimolar amounts by the parafollicular cells (C cells) of the thyroid gland. CT appears to be of little consequence in children and adults because very high levels in patients with medullary carcinoma of the thyroid (a tumor arising from the C cells) does not cause hypercalcemia. In the fetus, however, circulating levels are high

and appear to augment bone metabolism and skeletal growth; these high levels are probably stimulated by the normally high fetal calcium levels. Unlike the high levels in cord blood and circulating concentrations in young children, levels in older children and adults are low. Infants and children with congenital hypothyroidism (and presumed deficiency of C cells) have lower levels of CT than do normal children.

Its action appears to be independent of PTH and vitamin D. Its main biologic effect appears to be the inhibition of bone resorption by decreasing the number and activity of bone-resorbing osteoclasts. This action of CT is the rationale behind its use in treatment of Paget disease. CT is synthesized in other organs, such as the gastrointestinal tract, pancreas, brain, and pituitary. In these organs, CT is thought to behave as a neurotransmitter to impose a local inhibitory effect on cell function.

Chapter 565 - Hypoparathyroidism

Etiology (Box 565–1).

Hypocalcemia is common between 12–72?hr of life, especially in premature infants, in infants with asphyxia at birth, and in infants of diabetic mothers *(early neonatal hypocalcemia)* (see Chapter 95). After the 2nd–3rd day and during the 1st wk of life, the type of feeding is also a determinant of the level of serum calcium *(late neonatal hypocalcemia)*. The role played by the parathyroid glands in these hypocalcemic infants remains to be clarified, although functional immaturity of the parathyroid glands has often been invoked as one pathogenetic factor. In a group of infants with *transient idiopathic hypocalcemia* (1–8 wk of age), serum levels of parathyroid hormone (PTH) are significantly lower than those in normal infants. It is possible that the functional immaturity is a manifestation of a delay in development of the enzymes that convert glandular PTH to secreted PTH; other mechanisms are also possible.

APLASIA OR HYPOPLASIA OF THE PARATHYROID GLANDS.

This is often associated with the *DiGeorge/velocardiofacial syndrome* (see Fig. 564–1). This syndrome occurs in 1/4,000 newborns. In 90% of patients the condition is caused by a deletion of chromosome 22q11.2. Approximately 25% of these patients inherit the chromosomal abnormality from one of their parents. Neonatal hypocalcemia occurs in 60% of affected patients, but it is transitory in the majority; hypocalcemia may recur later or may have its onset later in life. Associated abnormalities of the 3rd and 4th pharyngeal pouches are common; these include conotruncal defects of the heart in 25%, velopharyngeal insufficiency in 32%, cleft palate in 9%, renal anomalies in 35%, and aplasia of the thymus with severe immunodeficiency in 1%. This syndrome has also been reported in a small number of patients with a deletion of chromosome 10p13, in infants of diabetic mothers, and in infants born to mothers treated with retinoic acid for acne early in pregnancy.

X-LINKED RECESSIVE HYPOPARATHYROIDISM.

Familial clusters of hypoparathyroidism with various patterns of transmission have been described. In two large North American pedigrees, this disorder appears to be transmitted by an *X-linked recessive gene* located on Xq26-q27. In these families, the onset of afebrile seizures characteristically occurs in infants from 2 wk–6 mo of age. The absence of parathyroid tissue after detailed examination of a boy with this condition suggests it is a defect in embryogenesis.

AUTOSOMAL RECESSIVE HYPOPARATHYROIDISM WITH DYSMORPHIC FEATURES.

This syndrome has been described in Middle Eastern children. Parental consanguinity occurred for almost all of several dozen affected patients. Profound hypocalcemia occurs early in life, and dysmorphic features include microcephaly, deep-set eyes, beaked nose, micrognathia, and large floppy ears. Intrauterine and postnatal growth retardation are severe, and mental retardation is common. The putative gene is on chromosome 1q42-43. The autosomal recessive form of hypoparathyroidism that occurs with type I polyglandular autoimmune disease is described subsequently. In a few patients with autosomal recessive inheritance of isolated hypoparathyroidism, mutations of the *PTH* gene have been found.

HDR SYNDROME.

Hypoparathyroidism, sensorineural *deafness* and *renal* anomaly occurs due to mutations of the *GATA3* gene. The protein encoded by this gene is essential in the development of the parathyroids, auditory system, and kidneys. The *GATA3* gene is located at chromosome 10p14 and is nonoverlapping with the DiGeorge critical region at 10p13 (see Fig. 564–1).

SUPPRESSION OF NEONATAL PTH SECRETION DUE TO MATERNAL HYPERPARATHYROIDISM.

This may result in transient hypocalcemia of the newborn infant. It appears that neonatal hypocalcemia results from suppression of the fetal

Box 565-1. Etiologic Classification of Hypocalcemia

Parathyroid hormone (PTH) deficiency

- Aplasia or hypoplasia of parathyroids
    - With 22q11 deletion
        - DiGeorge syndrome
        - Velocardiofacial syndrome
        - Conotruncal-face syndrome
    - With 10p13 deletion
    - With maternal diabetes mellitus or retinoic acid embryopathy
    - With X-linked isolated hypoparathyroidism
    - With mutation of *GCMB* (Glial Cell Missing B) autosomal recessive
    - With retardation and dysmorphism (Sanjad-Sakati syndrome) autosomal recessive
    - With deafness and renal dysplasia (*GATA3* mutation)
    - With osteosclerosis (Kenny-Caffey syndrome), TBCE mutation
- Suppression of neonatal PTH secretion due to maternal hyperparathyroidism
- Preproparathyroid hormone gene mutation
    - Autosomal dominant
- Ca^{2+} -sensing receptor activating mutation
    - Sporadic

Ca^{2+} -sensing receptor activating mutation

Sporadic

Autosomal dominant

Autoimmune parathyroiditis

Isolated

With type 1 autoimmune polyendocrinopathy, APECED

Mutation of *AIRE* gene

Infiltrative lesions

Hemosiderosis (treatment of thalassemia)

Copper deposition (Wilson disease)

PTH receptor defects (pseudohypoparathyroidism)

Type 1a (inactivating mutation of Gs_a)

With gonadotropin-independent precocious puberty

Type 1b (paternal imprinting of GNAS1)

Type 2 (normal cAMP response)

Mitochondrial DNA mutations

Kearns-Sayre syndrome

Pearson marrow pancreas syndrome

Mutation of long-chain 3-hydroxyacylcoenzyme A dehydrogenase

Magnesium deficiency

Renal magnesium loss (autosomal

Magnesium deficiency

Renal magnesium loss (autosomal dominant)

Magnesium malabsorption (autosomal recessive)

Aminoglycoside therapy

Exogenous inorganic phosphate excess

Laxatives

Soft drinks with phosphoric acid

Vitamin D deficiency

Nutritional

Vitamin D dependency (rickets)

Mutation of 1-a (OH)ase (P450)

parathyroid glands by exposure to elevated levels of calcium in maternal serum. Tetany usually develops within 3 wk but may be delayed 1 mo or more if the infant is breast-fed. Hypocalcemia may persist for weeks or months. When the cause of hypocalcemia in infants is unknown, measurements of calcium, phosphorus, and PTH should be obtained from the mothers. Most affected mothers are asymptomatic, and the cause of their hyperparathyroidism is usually a parathyroid adenoma.

AUTOSOMAL DOMINANT HYPOPARATHYROIDISM.

These patients have an activating (gain of function) mutation of the Ca^{2+} -sensing receptor, forcing the receptor to an “on” state with subsequent depression of PTH secretion even during hypocalcemia. The patients have hypercalciuria. The hypocalcemia is usually mild and may not require treatment beyond childhood (see Fig. 564–1).

HYPOPARATHYROIDISM ASSOCIATED WITH MITOCHONDRIAL DISORDERS.

Mitochondrial DNA mutations in Kearns-Sayre syndrome and in mitochondrial trifunctional protein have been associated with hypoparathyroidism. A diagnosis of mitochondrial cytopathy should be considered in patients with unexplained symptoms such as ophthalmoplegia, sensorineural hearing loss, cardiac conduction disturbances, and tetany (see Fig. 564–1).

SURGICAL HYPOPARATHYROIDISM.

Removal or damage of the parathyroid glands may complicate thyroidectomy. Hypoparathyroidism has developed even when the parathyroid glands have been identified and left undisturbed at the time of operation. This presumably is the result of interference with the blood supply or of postoperative edema and fibrosis. Symptoms of tetany may occur abruptly postoperatively and may be temporary or permanent. In some instances, symptoms may develop insidiously and go undetected until months after thyroidectomy. Occasionally, the first evidence of surgical hypoparathyroidism may be the development of cataracts. The status of parathyroid function should be carefully monitored in all patients undergoing thyroidectomy.

Deposition of iron pigment or of copper in the parathyroid glands (e.g., thalassemia, Wilson disease) may produce hypoparathyroidism.

AUTOIMMUNE HYPOPARATHYROIDISM.

An autoimmune mechanism for hypoparathyroidism is strongly suggested by the finding of parathyroid antibodies and by its frequent association with other autoimmune disorders or organ-specific antibodies. Autoimmune hypoparathyroidism is often associated with Addison disease and chronic mucocutaneous candidiasis. The association of at least two of these three conditions has been tentatively classified as *autoimmune polyglandular disease type I*. It is also known as *autoimmune polyendocrinopathy/candidiasis/ectodermal dystrophy*. This syndrome is inherited in an autosomal recessive fashion and is not related to any single HLA-associated haplotype. One third of patients with this syndrome have all three components; two thirds have only two of three conditions. The candidiasis almost always precedes the other disorders (70% of cases occur in children younger than 5 yr of age); the hypoparathyroidism (90% after 3 yr of age) usually occurs before Addison disease (90% after 6 yr of age). A variety of other disorders occur at various times and include alopecia areata or totalis, malabsorption disorder, pernicious anemia, gonadal failure, chronic active hepatitis, vitiligo, and insulin-dependent diabetes. Some of these associations may not appear until adult life. Autoimmune thyroid disease is a rare concomitant finding.

Affected siblings may have the same or different constellations of disorders (e.g., hypoparathyroidism and Addison disease). The disorder is exceptionally prevalent among Finns and Iranian Jews. The gene for this disorder is designated *AIRE* (autoimmune regulator); it is located on chromosome 21q22. It appears to be a transcription factor that plays an essential role in the development of immunologic tolerance. Patients with Addison disease as part of polyendocrinopathy syndrome type I have demonstrated adrenal-specific autoantibody reactivity directed against the side-chain cleavage enzyme.

IDIOPATHIC HYPOPARATHYROIDISM.

This term should be reserved for the small residuum of children with hypoparathyroidism for whom no causative mechanism can be defined. Most children in whom onset of hypoparathyroidism occurs after the first few years of life have an autoimmune condition. Autoantibodies to the extracellular domain of the calcium-sensing receptor have been identified in some patients with acquired hypoparathyroidism. One should always consider incomplete forms of DiGeorge syndrome or an activating calcium-sensing receptor mutation in the differential diagnosis.

Clinical Manifestations.

There is a spectrum of parathyroid deficiencies with clinical manifestations varying from no symptoms to those of complete and long-standing deficiency. Mild deficiency may be revealed only by appropriate laboratory studies. Muscular pain and cramps are early manifestations; they progress to numbness, stiffness, and tingling of the hands and feet. There may be only a positive Chvostek or Trousseau sign or laryngeal and carpopedal spasms. Convulsions with or without loss of consciousness may occur at intervals of days, weeks, or months. These episodes may begin with abdominal pain, followed by tonic rigidity, retraction of the head, and cyanosis. Hypoparathyroidism is frequently mistaken for epilepsy. Headache, vomiting, increased intracranial pressure, and papilledema may be associated with convulsions and may suggest a brain tumor.

In patients with long-standing hypocalcemia, the teeth erupt late and irregularly. Enamel formation is irregular, and the teeth may be unusually soft. The skin may be dry and scaly, and the nails of the fingers and toes may have horizontal lines. Mucocutaneous candidiasis, when present, antedates the development of hypoparathyroidism; the candidal infection most often involves the nails, the oral mucosa, the angles of the mouth, and, less often, the skin.

Cataracts in patients with long-standing untreated disease are a direct consequence of hypoparathyroidism; other autoimmune ocular disorders such as keratoconjunctivitis may also occur. Manifestations of Addison disease, lymphocytic thyroiditis, pernicious anemia, alopecia areata or totalis, hepatitis, and primary gonadal insufficiency may also be associated with those of hypoparathyroidism.

Permanent physical and mental deterioration occur if initiation of treatment is long delayed.

Laboratory Findings.

The serum calcium level is low (5–7?mg/dL), and the phosphorus level is elevated (7–12?mg/dL). Blood levels of ionized calcium (usually approximately 45% of the total) more nearly reflect physiologic adequacy but are also low. The serum level of alkaline phosphatase is normal or low, and the level of 1,25$[OH]_2$ D_3 is usually low, but high levels have been found in some children with severe hypocalcemia. The

level of magnesium is normal but should always be checked in hypocalcemic patients. Levels of PTH are low when measured by immunometric assay. Administration of the synthetic 1–34 fragment of human PTH (teriparatide acetate) results in increased urinary levels of cyclic adenosine monophosphate and phosphate. This response differentiates hypoparathyroidism from pseudohypoparathyroidism. With the advent of very sensitive PTH assays, this test is usually not necessary. Radiographs of the bones occasionally reveal an increased density limited to the metaphyses, suggestive of heavy metal poisoning, or an increased density of the lamina dura. Radiographs or CT of the skull may reveal calcifications in the basal ganglia. There is a prolongation of the QT interval on the electrocardiogram, which disappears when the hypocalcemia is corrected. The electroencephalogram usually reveals widespread slow activity; the

tracing returns to normal after the serum calcium concentration has been within the normal range for a few weeks, unless irreversible brain damage has occurred or unless the parathyroid insufficiency is associated with epilepsy. When hypoparathyroidism occurs concurrently with Addison disease, the serum level of calcium may be normal, but hypocalcemia appears after effective treatment of the adrenal insufficiency.

Treatment.

Emergency treatment of neonatal tetany consists of intravenous injections of 5–10?mL of a 10% solution of calcium gluconate at the rate of 0.5–1?mL/min while the heart rate is monitored. Additionally, 1,25-dihydroxycholecalciferol (calcitriol) should be given. The initial dosage is 0.25?µg/24?hr; the maintenance dosage ranges from 0.01–0.10?µg/kg/24?hr, to a maximum of 1–2?µg/24?hr. Calcitriol has a short half-life and should be given in two equal divided doses; it has the advantages of rapid onset of effect (1–4 days) and rapid reversal of hypercalcemia after discontinuation in the event of overdosage (i.e., calcium levels begin to fall in 3–4 days). Calcitriol is now supplied as an oral solution (1?µg/mL, Roche Pharmaceuticals).

After normocalcemia has been achieved, one may wish to continue therapy with vitamin D_2 because it is considerably less expensive than calcitriol. The usual dosage is 0.1–0.5?mg/24?hr in infants and young children. One milligram of vitamin D_2 has a biologic activity of 40,000?IU. Older children require 1.25–2.50?mg (50,000–100,000?IU) once daily. Vitamin D_2 has a slow onset of effect, and reversal of hypercalcemia after discontinuation of treatment is markedly delayed; its main advantage is its low cost.

An adequate intake of calcium should be ensured. Supplemental calcium can be given in the form of calcium gluconate or calcium glubionate (Neo-Calglucon) to provide 800?mg of elemental calcium daily, but it is rarely essential. Foods with a high phosphorus content such as milk, eggs, and cheese should be reduced in the diet.

Clinical evaluation of the patient and frequent determinations of the serum calcium levels are indicated in the early stages of treatment to determine the requirement for calcitriol or vitamin D_2 . If hypercalcemia occurs, therapy should be discontinued and resumed at a lower dose after the serum calcium level has returned to normal. In long-standing cases, repair of cerebral and dental changes is not likely. Pigmentation, lowering of the blood pressure, or weight loss may indicate adrenal insufficiency, which requires specific treatment. Patients with autosomal dominant hypocalcemic hypercalciuria may develop nephrocalcinosis and renal impairment if treated with vitamin D.

Differential Diagnosis.

Magnesium deficiency must be considered in patients with unexplained hypocalcemia. Concentrations of serum magnesium less than 1.5?mg/dL (1.2?mEq/L) are usually abnormal. *Familial hypomagnesemia* with secondary hypocalcemia has been reported in about 50 patients, most of whom developed tetany and seizures at 2–6 wk of age. Administration of calcium is ineffective, but administration of magnesium promptly corrects both calcium and magnesium levels. Oral supplements of magnesium are necessary to maintain levels of magnesium in the normal range. Two genetic forms have been described. One is caused by an autosomal recessive gene on chromosome 9, resulting in a specific defect in absorption of magnesium. The other is caused by an autosomal dominant gene on chromosome 11q23, resulting in renal loss of magnesium.

Hypomagnesemia also occurs in malabsorption syndromes such as granulomatous colitis and cystic fibrosis. Patients with autoimmune polyglandular disease type I and hypoparathyroidism may also have concurrent steatorrhea and low magnesium levels. Therapy with aminoglycosides causes hypomagnesemia by increasing urinary losses.

It is not clear how low levels of magnesium lead to hypocalcemia. Evidence suggests that hypomagnesemia impairs release of PTH and induces resistance to the effects of the hormone, but other mechanisms also may be operative.

Poisoning with inorganic phosphate leads to hypocalcemia and tetany. Infants administered large doses of inorganic phosphates, either as laxatives or as sodium phosphate enemas, have had sudden onset of tetany, with serum calcium levels less than 5?mg/dL and markedly elevated levels of phosphate. Symptoms are quickly relieved by intravenous administration of calcium. The mechanism of the hypocalcemia is not clear (see Chapter 48.9).

Hypocalcemia may occur early in the course of treatment of *acute lymphoblastic leukemia*. Hypocalcemia is usually associated with hyperphosphatemia resulting from destruction of lymphoblasts.

Episodic symptomatic hypocalcemia occurs in the *Kenny-Caffey syndrome*, which is characterized by medullary stenosis of the long bones, short stature, delayed closure of the fontanel, delayed bone age, and eye abnormalities. Idiopathic hypoparathyroidism and abnormal PTH levels have been found. Autosomal dominant and autosomal recessive modes of inheritance have been reported. Mutations of the

TBCE gene (1q 43-44) perturb microtubule organization in diseased cells.

Chapter 566 - Pseudohypoparathyroidism (Albright Hereditary Osteodystrophy)

In contrast to the situation in hypoparathyroidism, in pseudohypoparathyroidism (PHP), the parathyroid glands are normal or hyperplastic and they can synthesize and secrete parathyroid hormone (PTH). Serum levels of immunoreactive PTH are elevated even when the patient is hypocalcemic and may be elevated when the patient is normocalcemic. Neither endogenous nor administered PTH raises the serum levels of calcium or lowers the levels of phosphorus. The genetic defects in the hormone receptor adenylate cyclase system are classified into various types depending on the phenotypic and biochemical findings.

Type IA.

This type accounts for the majority of patients with PHP. Affected patients have a genetic defect of the a subunit of the stimulatory guanine nucleotide-binding protein (G_{sa}). This coupling factor is required for PTH bound to cell surface receptors to activate cyclic adenosine monophosphate (AMP). Heterogeneous mutations of the G_{sa} gene have been documented; the gene is located on chromosome 20q13.2. Deficiency of the G_{sa} subunit is a generalized cellular defect and accounts for the association of other endocrine disorders with type IA PHP. The defect is inherited as an autosomal dominant trait, and the paucity of father-to-son transmissions is thought to be due to decreased fertility in males.

Tetany is often the presenting sign. Affected children have a short, stocky build and a round face. Brachydactyly with dimpling of the dorsum of the hand is usually present. The 2nd metacarpal is involved least often. As a result, the index finger may occasionally be longer than the middle finger. Likewise, the 2nd metatarsal is only rarely affected. There may be other skeletal abnormalities such as short and wide phalanges, bowing, exostoses, and thickening of the calvaria. These patients frequently have calcium deposits and metaplastic bone formation subcutaneously. Moderate degrees of mental retardation, calcification of the basal ganglia, and lenticular cataracts are common in patients who are diagnosed late.

Some members of affected kindreds may have the usual anatomic stigmata of PHP, but serum levels of calcium and phosphorus are normal despite reduced G_{sa} activity; however, PTH levels may be slightly elevated. Such patients have been labeled as

having *pseudopseudohypoparathyroidism*. Transition from normocalcemia to hypocalcemia often occurs with increasing age of the patient. These phenotypically similar but metabolically dissimilar patients may occur in the same family and have the same mutations of G_{sa} protein. It is not known what other factors cause clinically overt hypocalcemia in some affected patients and not in others. There is some evidence to suggest that the G_{sa} mutation is paternally transmitted in pseudopseudohypoparathyroidism and maternally transmitted in patients with type Ia disease. The gene may be imprinted in a tissue-specific manner.

In addition to resistance to PTH, resistance to other G protein–coupled receptors for thyroid-stimulating hormone (TSH), gonadotropins, and glucagon may result in various metabolic effects. Clinical hypothyroidism is uncommon, but basal levels of TSH are elevated and thyrotropin-releasing hormone–stimulated TSH responses are exaggerated. Moderately decreased levels of thyroxine and increased levels of TSH have been detected by newborn thyroid screening programs, leading to the detection of type IA PHP in infancy. In adults, gonadal dysfunction is common, as manifested by sexual immaturity, amenorrhea, oligomenorrhea, and infertility. Each of these abnormalities can be related to deficient synthesis of cyclic AMP secondary to a deficiency of G_{sa} , but it is not clear why resistance to other G protein–dependent hormones (e.g., corticotropin, vasopressin) is much less affected.

Serum levels of calcium are low, and those of phosphorus and alkaline phosphatase are elevated. Clinical diagnosis can be confirmed by demonstration of a markedly attenuated response in urinary phosphate and cyclic AMP after intravenous infusion of the synthetic 1–34 fragment of human PTH (teriparatide acetate), but this compound is no longer commercially available in the United States. Definitive diagnosis is established by demonstration of the mutated G protein.

TYPE IA WITH PRECOCIOUS PUBERTY.

Two boys have been reported with both type IA PHP and gonadotropin-independent precocious puberty (see Chapter 556.6). They were found to have a temperature-sensitive mutation of the G_s protein. Thus, at normal body temperature (37°C), the G_s is degraded, resulting in PHP, but in the cooler temperature of the testes (33°C) the G_s mutation results in constitutive activation of the luteinizing hormone receptor and precocious puberty.

Type IB.

Affected patients have normal levels of G protein activity and a normal phenotypic appearance. These patients have tissue-specific resistance to PTH but not to other hormones. Serum levels of calcium, phosphorus, and immunoreactive PTH are the same as those in patients with type IA PHP. These patients also show no rise in cyclic AMP in response to exogenous administration of PTH. Bioactive PTH is not increased. The pathophysiology of the disorder in this group of patients is caused by paternal uniparental isodisomy of chromosome 20q and resulting GNAS1 methylation. This, along with the loss of the maternal *GNAS1* gene, leads to PTH resistance in the proximal renal tubules, which leads to impaired mineral ion homeostasis.

Type II.

This type of pseudohypoparathyroidism has been detected in only a few patients and differs from type I in that the urinary excretion of cyclic AMP is elevated both in the basal state and after stimulation with PTH, but phosphaturia does not increase. Phenotypically, patients are normal and hypocalcemia is present. The defect appears to be distal to cyclic AMP because it is normally activated, but the cell is unable to respond to the signal.

Chapter 567 - Hyperparathyroidism

Excessive production of parathyroid hormone (PTH) may result from a primary defect of the parathyroid glands such as an adenoma or hyperplasia *(primary hyperparathyroidism).*

More often, the increased production of PTH is compensatory, usually aimed at correcting hypocalcemic states of diverse origins *(secondary hyperparathyroidism).* In vitamin D–deficient rickets and the malabsorption syndromes, intestinal absorption of calcium is deficient but hypocalcemia and tetany may be averted by increased activity of the parathyroid glands. In pseudohypoparathyroidism, PTH levels are elevated because a mutation in the G_{sa} protein interferes with response to PTH. Early in chronic renal disease, hyperphosphatemia results in a reciprocal fall in the calcium concentration with a consequent increase in PTH, but in advanced stages of renal failure, production of $1,25[OH]_2 D_3$ is also decreased, leading to worsening hypocalcemia and further stimulation of PTH. In some instances, if stimulation of the parathyroid glands has been sufficiently intense and protracted, the glands may continue to secrete increased levels of PTH for months or years after renal transplantation, with resulting hypercalcemia.

Etiology.

Childhood hyperparathyroidism is rare. Onset during childhood is usually the result of a single benign adenoma. It usually becomes manifested after 10 yr of age. There have been a number of kindreds in which multiple members have hyperparathyroidism transmitted in an autosomal dominant fashion. Most of the affected family members are adults, but children have been involved in about a third of the pedigrees. Some affected patients in these families are asymptomatic and are detected only by careful study. In other kindreds, hyperparathyroidism occurs as part of the constellation known as the *multiple endocrine neoplasia (MEN) syndromes* or of the *hyperparathyroidism/ jaw tumor syndrome.*

Neonatal severe hyperparathyroidism has been reported in approximately 50 infants. Symptoms develop shortly after birth and consist of anorexia, irritability, lethargy, constipation, and failure to thrive. Radiographs reveal subperiosteal bone resorption, osteoporosis, and pathologic fractures. Symptoms may be mild, resolving without treatment, or may have a rapidly fatal course if diagnosis and treatment are delayed. Histologically, the parathyroid glands show diffuse hyperplasia. Affected siblings have been observed in some kindreds, and parental consanguinity has been reported in several kindreds. Most cases have occurred in kindreds with the clinical and biochemical features of *familial hypocalciuric hypercalcemia*. Infants with neonatal severe hyperparathyroidism may be homozygous or heterozygous for the mutation in the Ca^{2+} -sensing receptor gene, whereas most individuals with one copy of this mutation exhibit autosomally dominant familial hypocalciuric hypercalcemia.

MEN type I is an autosomal dominant disorder characterized by hyperplasia or neoplasia of the endocrine pancreas (which secretes gastrin, insulin, pancreatic polypeptide, or occasionally glucagon), the anterior pituitary (which usually secretes prolactin), and the parathyroid glands. In most kindreds, hyperparathyroidism is usually the presenting manifestation, with a prevalence approaching 100% by 50 yr of age but occurring only rarely in children younger than 18 yr of age. In the past, after an affected family was identified, it was necessary to perform repeated metabolic screening for many years to detect other affected family members. With appropriate DNA probes, it is now possible to detect carriers of the gene with 99% accuracy at birth, avoiding unnecessary biochemical screening programs.

The gene for MEN type I is on chromosome 11q13; it appears to function as a tumor suppressor gene and follows the two-hit hypothesis of tumor development. The first mutation (germinal) is inherited and is recessive to the dominant allele; this does not result in tumor formation. A second mutation (somatic) is required to eliminate the normal allele, which then leads to tumor formation.

Hyperparathyroidism/jaw tumor syndrome is an autosomal dominant disorder characterized by parathyroid adenomas and fibro-osseous jaw tumors. Affected patients may also have polycystic kidney disease, renal hamartomas, and Wilms tumor. Although the condition affects adults primarily, it has been diagnosed as early as age 10 yr.

MEN type II may also be associated with hyperparathyroidism (see Chapter 563.2).

Transient neonatal hyperparathyroidism has occurred in a few infants born to mothers with hypoparathyroidism (idiopathic or surgical) or with pseudohypoparathyroidism. In each case, the maternal disorder had been undiagnosed or inadequately treated during pregnancy. The cause of the condition is chronic intrauterine exposure to hypocalcemia with resultant hyperplasia of the fetal parathyroid glands. In the newborn, manifestations involve the bones primarily and healing occurs between 4 and 7 mo of age.

Clinical Manifestations.

At all ages, the clinical manifestations of hypercalcemia of any cause include muscular weakness, anorexia, nausea, vomiting, constipation, polydipsia, polyuria, loss of weight, and fever. When hypercalcemia is of long duration, calcium may be deposited in the renal parenchyma (nephrocalcinosis), with progressively diminished renal function. Renal calculi may occur and may produce renal colic and hematuria. Osseous changes may produce pain in the back or extremities, disturbances of gait, genu valgum, fractures, and tumors. Height may decrease from compression of vertebrae; the patient may become bedridden. Detection of completely asymptomatic patients is increasing with the advent of automated panel assays that include serum

calcium determinations.

Abdominal pain is occasionally prominent and may be associated with acute pancreatitis. Parathyroid crisis may occur, manifested by serum calcium levels greater than 15?mg/dL and progressive oliguria, azotemia, stupor, and coma. In infants, failure to thrive, poor feeding, and hypotonia are common. Mental retardation, convulsions, and blindness may occur as sequelae of long-standing hypercalcemia.

Laboratory Findings.

The serum calcium level is elevated; 39 of 45 children with adenomas had levels greater than 12?mg/dL. The hypercalcemia is more severe in infants with parathyroid hyperplasia; concentrations ranging from 15–20?mg/dL are common, and values as high as 30?mg/dL have been reported. Even when the total serum calcium level is borderline or only slightly elevated, ionized calcium levels are often increased. The serum phosphorus level is reduced to about 3?mg/dL or less, and the level of serum magnesium is low. The urine may have a low and fixed specific gravity, and serum levels of nonprotein nitrogen and uric acid may be elevated. In patients with adenomas who have skeletal involvement, serum phosphatase levels are elevated, but in infants with hyperplasia the levels of alkaline phosphatase may be normal even when there is extensive involvement of bone.

Serum levels of PTH measured by carboxy-terminal antisera are elevated, especially in relation to the level of calcium. Results may vary markedly from one laboratory to another, depending on the antibody used. Calcitonin levels are normal. Acute hypercalcemia can stimulate calcitonin release; but with prolonged hypercalcemia, hypercalcitoninemia does not occur.

The most consistent and characteristic radiographic finding is resorption of subperiosteal bone, best seen along the margins of the phalanges of the hands. In the skull, there may be gross trabeculation or a granular appearance resulting from focal rarefaction; the lamina dura may be absent. In more advanced disease, there may be generalized rarefaction, cysts, tumors, fractures, and deformities. About 10% of patients have radiographic signs of rickets. Radiographs of the abdomen may reveal renal calculi or nephrocalcinosis.

Differential Diagnosis.

Other causes of hypercalcemia may result in a similar clinical pattern and must be differentiated from hyperparathyroidism (Box 567–1). A low serum phosphorus level with hypercalcemia is characteristic of primary hyperparathyroidism; elevated levels of PTH are also diagnostic. With hypercalcemia of any cause except hyperparathyroidism and familial hypocalciuric hypercalcemia, PTH levels are suppressed. Pharmacologic doses of corticosteroids lower the serum calcium level to normal in patients with hypercalcemia from other causes but generally do not affect the calcium level in patients with hyperparathyroidism.

Treatment.

Surgical exploration is indicated in all instances. All glands should be carefully inspected; if an adenoma is discovered, it should be removed; very few instances of carcinoma are known in children. Most neonates with severe hypercalcemia require total parathyroidectomy; less severe hypercalcemia may remit spontaneously in others. A portion of a parathyroid gland may be autografted into the forearm; four infants treated in this fashion were able to maintain normocalcemia without supplementary treatment, but no long-term outcome has yet been reported. The patient should be carefully observed postoperatively for the development of hypocalcemia and tetany; intravenous administration of calcium gluconate may be required for a few days. The serum calcium level then gradually returns to normal, and, under

Box 567-1. Etiologic Classification of Hypercalcemia

Parathyroid hormone (PTH) excess

- Primary hyperparathyroidism
  - Adenoma
    - Sporadic
    - Autosomal dominant
    - Hyperparathyroidism-jaw tumor syndrome
  - Hyperplasia or adenoma
    - Multiple endocrine neoplasia type1
      - Mutation in *MEN1* gene (11q13)
    - Parathyroid hyperplasia of infancy
      - Inactivating mutation of Ca^{2+} -sensing receptor
      - Secondary to maternal hypoparathyroidism
  - Ectopic PTH production
    - Nonendocrine malignancies

Ectopic PTH production

Nonendocrine malignancies

Parathyroid hormone–related peptide (PTHrP) excess

Nonendocrine malignancies

Benign hypertrophy of breasts

Ca^{2+} -sensing receptor inactivating mutation

Heterozygous-familial hypocalciuric hypercalcemia

Neonatal severe hyperparathyroidism

Activating mutation of PTH/PTHrP receptor

Autosomal dominant

Jasen-type metaphyseal chondrodysplasia

Inactivating mutation of PTH/PTHrP receptor

Autosomal recessive

Blomstrand chondrodysplasia

Vitamin D excess

Iatrogenic

Ectopic production

Sarcoidosis, tuberculosis, granulomatous lesions, subcutaneous fat necrosis

Excessively fortified milk

granulomatous lesions, subcutaneous fat necrosis

Excessively fortified milk

Unknown cause

Williams syndrome (7q11.23 deletion)

Other

Hypophosphatasia

Mutation of tissue nonspecific alkaline phosphatase gene

Prolonged immobilization

Thyrotoxicosis

Hypervitaminosis A

Leukemia

ordinary circumstances, a diet high in calcium and phosphorus must be maintained for only several months after operation.

Arteriography and selective venous sampling with radioimmunoassay of PTH for preoperative localization and differentiation of a single adenoma from hyperplasia have been replaced by imaging methods. CT, real-time ultrasonography, and subtraction scintigraphy using sestamibi/Tc-pertechnetate alone and in combination have proved effective in 50–90% of adults. These procedures are rarely required by the expert parathyroid surgeon but may be advisable before re-exploration in cases of persistent or recurrent hyperparathyroidism.

Prognosis.

The prognosis is good if the disease is recognized early and there is appropriate surgical treatment. When extensive osseous lesions are present, deformities may be permanent. A search for other affected family members is indicated.

Other Causes of Hypercalcemia

FAMILIAL HYPOCALCIURIC HYPERCALCEMIA (FAMILIAL BENIGN HYPERCALCEMIA).

Patients with this disorder are usually asymptomatic, and the hypercalcemia comes to light by chance during routine investigation for other conditions. The parathyroid glands are normal, PTH levels are inappropriately normal, and subtotal parathyroidectomy does not correct the hypercalcemia. Serum levels of magnesium are high normal or mildly elevated. The rate of calcium to creatinine clearance is usually decreased despite hypercalcemia. The disorder is inherited in an autosomal dominant manner and is caused by a mutant gene on chromosome 3q2. Penetrance is near 100%, and affected individuals can be diagnosed early in childhood by serum and urinary calcium concentrations. Detection of other affected family members is important to avoid inappropriate parathyroid surgery. The basic defect in this condition results from inactivating mutations in the Ca^{2+} -sensing receptor gene. This G protein–coupled receptor senses the level of free Ca^{2+} in the blood and triggers the pathway to increase extracellular Ca^{2+} in the face of hypocalcemia. This receptor functions in the parathyroid and kidney to regulate calcium homeostasis; inactivating mutations lead to an increased set point with respect to serum Ca^{2+} , resulting in mild to moderate hypercalcemia in heterozygotes.

GRANULOMATOUS DISEASES.

Hypercalcemia occurs in 30–50% of children with sarcoidosis and less often in patients with other granulomatous diseases such as tuberculosis. Levels of PTH are suppressed, and levels of 1,25[OH]$_2$ D$_3$ are elevated. The source of ectopic 1,25[OH]$_2$ D$_3$ is the activated macrophage, through stimulation by interferon-a from T lymphocytes, which are present in abundance in granulomatous lesions. Unlike renal tubular cells, the 1a-hydroxylase in macrophages is unresponsive to homeostatic regulation. Oral administration of prednisone (2?mg/kg/24?hr) lowers serum levels of 1,25[OH]$_2$ D$_3$ to normal and corrects the hypercalcemia.

HYPERCALCEMIA OF MALIGNANCY.

Hypercalcemia frequently occurs in adults with a wide variety of solid tumors but is identified much less often in children. It has been reported in infants with malignant rhabdoid tumors of the kidney or congenital mesoblastic nephroma and in children with neuroblastoma, medulloblastoma, leukemia, Burkitt lymphoma, dysgerminoma, and rhabdomyosarcoma. Serum levels of PTH are rarely elevated. In most patients, the hypercalcemia associated with malignancy is caused by elevated levels of parathyroid hormone–related peptide (PTHrP) and not PTH. Rarely, tumors produce 1,25[OH]$_2$ D$_3$ or PTH ectopically.

MISCELLANEOUS CAUSES OF HYPERCALCEMIA.

Hypercalcemia may occur in infants with subcutaneous *fat necrosis*. Levels of PTH are normal. In one infant, the level of 1,25[OH]$_2$ D$_3$ was elevated and biopsy of the skin lesion revealed granulomatous infiltration, suggesting that the mechanism of the hypercalcemia was akin to that seen in patients with other granulomatous disease. In another infant, although the level of 1,25[OH]$_2$ D$_3$ was normal, PTH was suppressed, suggesting the hypercalcemia was not PTH related. Treatment with prednisone is effective.

Hypophosphatasia, especially the severe infantile form, is usually associated with mild to moderate hypercalcemia (see Chapter 694). Serum levels of phosphorus are normal, and those of alkaline phosphatase are subnormal. The bones exhibit rachitic-like lesions on radiographs. Urinary levels of phosphoethanolamine, inorganic pyrophosphate, and pyridoxal 5'-phosphate are elevated; each is a natural substrate to a *tissue-nonspecific* (liver, bone, kidney) *alkaline phosphatase enzyme*. Missense mutations of the tissue-nonspecific alkaline phosphatase enzyme gene result in an inactive enzyme in this autosomal recessive disorder.

Idiopathic hypercalcemia of infancy is manifested by failure to thrive and hypercalcemia during the 1st yr of life, followed by spontaneous remission. Serum levels of phosphorus and PTH are normal. The hypercalcemia results from increased absorption of calcium. Vitamin D may be involved in the pathogenesis. Both normal and elevated levels of 1,25[OH]$_2$ D$_3$ have been reported. An excessive rise in the level of 1,25[OH]$_2$ D$_3$ in response to PTH administration years after the hypercalcemic phase suggests that vitamin D has a role in the pathogenesis. A blunted calcitonin response to intravenous calcium has also been reported.

Ten per cent of patients with *Williams syndrome* also exhibit associated infantile hypercalcemia. The phenotype consists of feeding difficulties, slow growth, elfin facies, renovascular disorders, and a gregarious personality. The IQ score of 50 to 70 is curiously accompanied by enhanced quantity and quality of vocabulary, auditory memory, and social use of language. A submicroscopic deletion at chromosome 7q11.23, which includes deletion of one elastin allele, occurs in 90% of patients and seems to account for the vascular problems. Definitive diagnosis can be established by specific fluorescent in situ hybridization. The hypercalcemia and central nervous system symptoms may be caused by deletion of adjacent genes. Hypercalcemia has been successfully controlled with either prednisone or calcitonin.

Hypervitaminosis D resulting in hypercalcemia from drinking milk that has been incorrectly fortified with vitamin D has been reported. Serum levels of 25[OH]D are a better indicator of hypervitaminosis D than 1,25[OH]$_2$ D$_3$ because 25[OH]D has a longer half-life.

Prolonged immobilization may lead to hypercalcemia and occasionally to decreased renal function, hypertension, and encephalopathy. Children having hypophosphatemic rickets and undergoing surgery with subsequent long-term immobilization are at risk for hypercalcemia and should therefore have their vitamin D supplementation decreased or discontinued.

Jansen-type metaphyseal chondrodysplasia is a rare genetic disorder characterized by short-limbed dwarfism and severe but asymptomatic hypercalcemia (see Chapter 692). Circulating levels of PTH and PTHrP are undetectable. These patients have an activating PTH-PTHrP receptor mutation that results in aberrant calcium homeostasis and abnormalities of the growth plate.

Section 4 - *Disorders of the Adrenal Glands*

Lenore S. Levine
Perrin C. White

Chapter 568 - The Physiology of the Adrenal Gland

568.1 Histology and Embryology

The adrenal gland is composed of two endocrine tissues, the medulla and the cortex. The chromaffin cells of the adrenal medulla are derived from neuroectoderm, whereas the cells of the adrenal cortex are derived from mesoderm. Mesodermal cells also contribute to the development of the gonads. The adrenal glands and gonads have certain common enzymes involved in steroid synthesis; an inborn error in steroidogenesis in one tissue may also be present in the other.

The adrenal cortex consists of three zones: the zona glomerulosa, the outermost zone located immediately beneath the capsule; the zona fasciculata, the middle zone; and the zona reticularis, the innermost zone, lying next to the adrenal medulla. The zona fasciculata is the largest of the zones, constituting about three fourths of the cortex; the zona glomerulosa comprises about 15% and the zona reticularis about 10%. Glomerulosa cells are small with a lower cytoplasmic:nuclear ratio, intermediate number of lipid inclusions, and smaller nuclei containing more condensed chromatin than the cells of the other two zones. The cells of the zona fasciculata are large with a high cytoplasmic:nuclear ratio and many lipid inclusions

that give the cytoplasm a foamy, vacuolated appearance. The cells are arranged in radial cords. The cells of the zona reticularis are arranged in irregular anastomosing cords. The cytoplasmic:nuclear ratio is intermediate, and the compact cytoplasm has relatively little lipid content.

The zona glomerulosa synthesizes aldosterone, the most potent natural mineralocorticoid in humans. The zona fasciculata produces cortisol, the most potent natural glucocorticoid in humans, and the zona fasciculata and zona reticularis synthesize the adrenal androgens.

The adrenal medulla consists mainly of neuroendocrine (chromaffin) cells and glial (sustentacular) cells with some connective tissue and vascular cells. Neuroendocrine cells are polyhedral with abundant cytoplasm and small, pale-staining nuclei. Under the electron microscope, the cytoplasm contains many large secretory granules that contain catecholamines. Glial cells have less cytoplasm and more basophilic nuclei.

The primordium of the fetal adrenal gland can be recognized at 3–4 wk of gestation just cephalad to the developing mesonephros. At 5–6 wk, the gonadal ridge develops into the steroidogenic cells of the gonads and adrenal cortex; the adrenal and gonadal cells separate, the adrenal cells migrate retroperitoneally, and the gonadal cells migrate caudad. At 6–8 wk of gestation, the gland rapidly enlarges, the cells of the inner cortex differentiate to form the fetal zone, and the outer subcapsular rim remains as the definitive zone. The primordium of the adrenal cortex is invaded at this time by sympathetic neural elements that differentiate into the chromaffin cells capable of synthesizing and storing catecholamines. Catechol-O-methyltransferase, which converts norepinephrine to epinephrine, is expressed later in gestation. By the end of the 8th wk of gestation, the encapsulated adrenal gland is associated with the upper pole of the kidney. By 9–12 wk of gestation, the cells of the fetal zone are capable of active steroidogenesis. In the fetus of 2 mo, the adrenals are larger than the kidneys, but from the 4th mo, the kidneys grow rapidly, becoming twice as large as the adrenals by the end of the 6th mo. In the full-term infant, the adrenal gland is one third of the size of the kidney and the combined weight of both glands is 7–9?g. At birth, the inner fetal cortex makes up about 80% of the gland and the outer "true" cortex, 20%. Within a few days the fetal cortex begins to involute, undergoing a 50% reduction by 1 mo of age. Conversely, the adrenal medulla is relatively small at birth and undergoes a proportionate increase in size over the first 6 postnatal months. By 1 yr, the adrenal glands each weigh less than 1?g. Adrenal growth thereafter results in adult adrenal glands reaching a combined weight of 8?g. The zonae fasciculata and glomerulosa are fully differentiated by about 3 yr of age. The zona reticularis may not be fully differentiated until puberty.

Early fetal adrenal growth appears to be independent of adrenocorticotropic hormone (ACTH), but, at least from midterm until term, ACTH is essential for adrenal growth and maturation. At which stage of fetal development feedback regulation of ACTH by cortisol is established has not been fully defined, but clinical experience suggests that normal pituitary-adrenal feedback relationships are operative in the first trimester. Additional factors important in fetal growth and steroidogenesis include placental chorionic gonadotropins and a number of peptide growth factors produced by the placenta and fetus.

Two transcription factors are critical for the development of the adrenal glands: steroidogenic factor-1 (SF-1) and DAX-1 (*d*osage-sensitive sex reversal, *a*drenal hypoplasia congenita, *X*-chromosome). SF-1 is also important in the transcriptional regulation of several genes coding for enzymes of steroidogenesis. Disruption of SF-1, encoded on chromosome 9q33, results in adrenal and gonadal agenesis, absence of pituitary gonadotropes, and an underdeveloped ventral medial hypothalamus. Mutations in the *DAX1* gene, encoded on Xp21, result in congenital adrenal hypoplasia and hypogonadotropic hypogonadism. DAX-1 also plays an important role in regulating steroidogenesis.

568.2 Adrenal Steroid Biosynthesis

Cholesterol is the starting substrate for all steroid biosynthesis (Fig. 568–1). Although adrenal steroid cells can synthesize cholesterol de novo from acetate, 80% of the cholesterol precursor for adrenal cortex hormone formation is provided by the circulating plasma lipoproteins. Specific cell surface receptors for low-density lipoprotein (LDL) bind the circulating LDL and internalize it by receptor-mediated endocytosis. Cholesterol is stored as cholesteryl esters in vesicles and subsequently hydrolyzed by cholesteryl ester hydrolase to liberate free cholesterol to be used for steroid hormone synthesis.

The rate-limiting step of adrenal steroidogenesis is importation of cholesterol across the mitochondrial outer and inner membrane. This requires several proteins, including the peripheral benzodiazepine receptor and the steroidogenic acute regulatory (StAR) protein. StAR protein has a very short half-life, and its synthesis is rapidly induced by trophic factors (e.g., corticotropin); thus, it is the main short-term (min to hr) regulator of steroid hormone biosynthesis.

At the mitochondrial inner membrane, the side-chain of cholesterol is cleaved to yield pregnenolone. This is catalyzed by cholesterol side-chain cleavage enzyme (cholesterol desmolase, P450scc, CYP11A1), a cytochrome P450 (CYP) enzyme. Like other P450s, this is a membrane-bound hemoprotein with a molecular mass of about 50?kd. It accepts electrons from an NADPH-dependent mitochondrial electron transport system consisting of two accessory proteins, adrenodoxin reductase (a flavoprotein) and adrenodoxin (a small protein containing nonheme iron). P450 enzymes utilize electrons and O_2 to hydroxylate the substrate and form H_2O. In the case of the cholesterol side-chain cleavage reaction, three successive oxidative reactions are performed to cleave the C20,22 carbon bond. Pregnenolone then diffuses out of mitochondria and enters the endoplasmic reticulum. The subsequent reactions that occur depend on the zone of the adrenal cortex.

Zona Glomerulosa.

In the zona glomerulosa, pregnenolone is converted to progesterone by 3ß-hydroxysteroid dehydrogenase (HSD3B2), an NAD^+ -dependent enzyme of the “short chain dehydrogenase” type. Progesterone is converted to 11-deoxycorticosterone by steroid 21-hydroxylase (P450c21, CYP21), which is another cytochrome P450. Like other P450s in the endoplasmic reticulum, it utilizes an electron transport system with only one accessory protein, cytochrome P450 reductase.

Deoxycorticosterone then re-enters mitochondria and is converted to aldosterone by aldosterone synthase (P450aldo, CYP11B2), another P450 enzyme structurally related to cholesterol desmolase. Aldosterone synthase also carries out three successive oxidations: 11ß-hydroxylation, 18-hydroxylation, and further oxidation of the 18-methyl carbon to an aldehyde.

Zona Fasciculata.

In the endoplasmic reticulum of the zona fasciculata, pregnenolone and progesterone are converted by 17a-hydroxylase (P450c17, CYP17) to 17-hydroxypregenolone and 17-hydroxyprogesterone, respectively. This enzyme is not expressed in the zona glomerulosa, which consequently cannot synthesize 17-hydroxylated steroids. 17-Hydroxypregnenolone is converted to 17-hydroxyprogesterone and 11-deoxycortisol by the same 3ß-hydroxysteroid and 21-hydroxylase enzymes, respectively, as are active in the zona glomerulosa. Thus, inherited disorders in these enzymes affect both aldosterone and cortisol synthesis (see Chapter 570). Finally, 11-deoxycortisol re-enters mitochondria and is converted to cortisol by steroid 11ß-hydroxylase (P450c11, CYP11B1). This enzyme is closely related to aldosterone synthase but has low 18-hydroxylase and nonexistent 18-oxidase

Figure 568.2-1 Pathways of steroid biosynthesis. The pathways for adrenal synthesis of mineralocorticoids (aldosterone), glucocorticoids (cortisol) and androgens (DHEA, androstenedione) are arranged vertically. The enzymatic activity for each bioconversion is indicated. The systematic name for the activities mediated by specific cytochromes P450 is indicated in parentheses. The reactions shown with dotted arrows occur primarily in gonads, not in adrenals. P450c11ß mediates 11ß-hydroxylase activity in the zona fasciculata to convert DOC to corticosterone and 11-deoxycortisol to cortisol. P450c18 mediates 11ß-hydroxylase, 18-hydroxylase and 18-oxidase activities in the zona glomerulosa for the conversion of DOC to aldosterone.

activity. Thus, under normal circumstances the zona fasciculata cannot synthesize aldosterone.

Zona Reticularis.

In the zona reticularis and to some extent in the zona fasciculata, the 17-hydroxylase (CYP17) enzyme has an additional activity, cleavage of the 17,20 carbon-carbon bond. This converts 17-hydroxypregnenolone to dehydroepiandrosterone (DHEA). Dehydroepiandrosterone is converted by 3ß-hydroxysteroid dehydrogenase to androstenedione. This may be further converted in other tissues to testosterone and estrogens.

Fetoplacental Unit.

Steroid synthesis in the fetal adrenal differs from that in the postnatal gland. LDL cholesterol synthesized by the fetal liver is the major cholesterol source for steroid synthesis in the fetal adrenal gland. The fetal adrenal gland has low 3ß-hydroxysteroid dehydrogenase activity and high steroid sulfokinase activity. Thus, the major steroid products of the fetal adrenal gland are DHEA and DHEA sulfate (DHEAS) and, by 16a-hydroxylation in the liver, 16a-hydroxy DHEAS. The placenta, which has high steroid sulfatase activity, uses DHEA and DHEAS as substrates for estrone and estradiol and 16a-OH DHEAS as a substrate for estriol. Placental estrone and estradiol are derived equally from fetal and maternal precursors; estriol is almost exclusively produced from substrates of fetal origin. In addition to providing substrate for the placental synthesis of estrogens, the fetal adrenal gland also

produces significant amounts of cortisol, much of which is converted to cortisone by the enzyme 11ß-hydroxysteroid dehydrogenase. As term approaches, fetal cortisol concentration increases as a result of increased cortisol secretion and decreased conversion of cortisol to cortisone. Low levels of aldosterone are produced in mid gestation, but aldosterone secretory capacity increases near term.

568.3 Regulation of the Adrenal Cortex

Regulation of Cortisol Secretion.

Glucocorticoid secretion is regulated mainly by adrenocorticotropic hormone (corticotropin, ACTH), a 39-amino acid peptide that is produced in the anterior pituitary. It is synthesized as part of a larger molecular weight precursor peptide known as pro-opiomelanocortin (POMC). This precursor peptide is also the source of ß-lipotropin (ß-LPH). In addition, ACTH and ß-LPH are cleaved further to yield a- and ß-melanocyte-stimulating hormone, corticotropin-like

intermediate lobe peptide (CLIP), ?-LPH, ß- and ?-endorphin, and enkephalin (see Chapter 550).

ACTH is released in secretory bursts of varying amplitude throughout the day and night. The normal diurnal rhythm of cortisol secretion is caused by the varying amplitudes of ACTH pulses. Pulses of ACTH and cortisol occur every 30–120?min, are highest at about the time of waking, are low in late afternoon and evening, and reach their lowest point 1 or 2?hr after sleep begins.

Corticotropin-releasing hormone (CRH), synthesized by neurons of the parvicellular division of the hypothalamic paraventricular nucleus, is the most important stimulator of ACTH secretion. Arginine vasopressin (AVP) augments CRH action. Neural stimuli from the brain cause the release of CRH and AVP (see Chapter 550). AVP and CRH are secreted in the hypophyseal-portal circulation in a pulsatile manner. This pulsatile secretion appears to be responsible for the pulsatile (ultradian) release of ACTH. The circadian rhythm of corticotropin release is probably induced by a corresponding circadian rhythm of hypothalamic CRH secretion, regulated by the suprachiasmatic nucleus with input from other areas of the brain. Cortisol exerts a negative feedback effect on the synthesis and secretion of ACTH, CRH, and AVP. ACTH inhibits its own secretion, a feedback effect mediated at the level of the hypothalamus. Thus the secretion of cortisol is a result of the interaction of the hypothalamus, pituitary, and adrenal glands and other neural stimuli.

ACTH acts through a specific G protein–coupled receptor to activate adenylate cyclase and increase levels of cyclic adenosine monophosphate (AMP). Cyclic AMP has short-term (minutes to hours) effects on cholesterol transport into mitochondria by increasing expression of steroidogenesis acute regulatory (StAR) protein. The long-term effects (hours to days) of ACTH stimulation are to increase the uptake of LDL cholesterol and the expression of genes encoding the enzymes required to synthesize cortisol. These transcriptional effects occur at least in part through increased activity of protein kinase A, which phosphorylates several transcriptional regulatory factors.

Regulation of Aldosterone Secretion.

The rate of aldosterone synthesis, which is normally 100- to 1000-fold less than that of cortisol synthesis, is regulated mainly by the renin-angiotensin system and by potassium levels, with ACTH having only a short-term effect. In response to decreased intravascular volume, renin is secreted by the juxtaglomerular apparatus of the kidney. Renin is a proteolytic enzyme that cleaves angiotensinogen (renin substrate), an a_2 -globulin produced by the liver, to yield the inactive decapeptide angiotensin I. Angiotensin-converting enzyme in the lungs and other tissues rapidly cleaves angiotensin I to the biologically active octapeptide angiotensin II. Cleavage of angiotensin II produces the heptapeptide angiotensin III. Angiotensin II and III are potent stimulators of aldosterone secretion; angiotensin II is a more potent vasopressor agent. Angiotensin II and III occupy a G protein–coupled receptor activating phospholipase C. The latter protein hydrolyzes phosphatidylinositol bisphosphate to produce inositol triphosphate and diacylglycerol, which raise intracellular calcium levels and activate protein kinase C and calmodulin-activated (CaM) kinases. Similarly, increased levels of extracellular potassium depolarize the cell membrane and increase calcium influx through voltage-gated L-type calcium channels. Phosphorylation of as yet unidentified factors by CaM kinases increases transcription of the aldosterone synthase (CYP11B2) enzyme required for aldosterone synthesis.

Regulation of Adrenal Androgen Secretion.

The mechanisms by which the adrenal androgens dehydroepiandrosterone and androstenedione are regulated are not completely understood. *Adrenarche* is a maturational process in the adrenal gland that results in increased adrenal androgen secretion between the ages of 5 and 20 years. The process begins before the earliest signs of puberty and continues throughout the years when puberty is occurring. Histologically, it is associated with the appearance of the zona reticularis. Whereas ACTH stimulates adrenal androgen production acutely and clearly is the primary stimulus for cortisol release (see later), additional factors have been implicated in the stimulation of the adrenal androgens. These include a relative decrease in expression of 3ß- hydroxysteroid dehydrogenase in the zona reticularis and possibly increases in 17,20-lyase activity owing to phosphorylation or increased cytochrome b5 expression.

568.4 Adrenal Steroid Hormone Actions

Steroid hormones act through several distinct receptors corresponding to the known biologic activities of the steroid hormones: glucocorticoid, mineralocorticoid, progestin, estrogen, and androgen. These receptors belong to a larger superfamily of nuclear transcriptional factors that include, among others, thyroid hormone and retinoic acid receptors. They have a common structure that includes a carboxy-terminal ligand-binding domain and a mid-region DNA-binding domain. The latter domain contains two “zinc fingers,” each of which consists of a loop of amino acids stabilized by four cysteine residues chelating a zinc ion.

Unliganded glucocorticoid and mineralocorticoid receptors are found mainly in the cytosol. Hormone molecules diffuse through the cell membrane and bind receptors, changing their conformation and causing them to be translocated to the nucleus where they bind DNA at specific hormone response elements. Bound receptors may recruit other transcriptional co-regulatory factors to DNA.

Whereas different steroids may share bioactivities because of their ability to bind to the same receptor, a given steroid may exert diverse biologic effects in different tissues. The diversity of hormonal responses is determined by the different genes that are regulated by the hormone in different tissues. Additionally, different combinations of co-regulators are expressed in different tissues, allowing each steroid hormone to have many different effects. Moreover, enzymes may increase or decrease the affinity of steroids for their receptors and thus modulate their activity.

Actions of Glucocorticoids.

Glucocorticoids are essential for survival. The term *glucocorticoid* refers to the glucose-regulating properties of these hormones. However, the glucocorticoids have multiple effects on carbohydrate, lipid, and protein metabolism. They also regulate immune, circulatory, and renal function. They influence growth, development, bone metabolism, and central nervous system activity.

In stress situations, glucocorticoid secretion can increase up to 10-fold. This increase is believed to enhance survival through increased cardiac contractility, cardiac output, sensitivity to the pressor effects of the catecholamines and other pressor hormones, work capacity of the skeletal muscles, and capacity to mobilize energy stores.

METABOLIC EFFECTS.

The primary action of the glucocorticoids on carbohydrate metabolism is to increase glucose production by increasing hepatic gluconeogenesis. In addition to inducing gluconeogenic enzymes, glucocorticoids stimulate glycolysis, proteolysis, and lipolysis, which provides more substrate for gluconeogenesis. Glucocorticoids also increase cellular resistance to insulin, thereby decreasing entry of glucose into the cell. This inhibition of glucose uptake occurs in adipocytes, muscle cells, and fibroblasts. In addition to opposing insulin action, glucocorticoids may work in parallel with insulin to protect against long-term starvation by stimulating glycogen deposition and production in liver. Both hormones

stimulate glycogen synthetase activity and decrease glycogen breakdown.

Thus, glucocorticoid excess may cause hyperglycemia, whereas glucocorticoid deficiency may cause hypoglycemia.

Glucocorticoids increase free fatty acid levels by enhancing lipolysis, decreasing cellular glucose uptake and decreasing glycerol production, which is necessary for re-esterification of fatty acids. This increase in lipolysis is also stimulated through the permissive enhancement of lipolytic action of other factors such as epinephrine. This action affects adipocytes differently according to their anatomic locations. In the patient with glucocorticoid excess, fat is lost in the extremities, but it is increased in the trunk (centripetal obesity), neck, and face (moon facies). This may involve effects on adipocyte differentiation.

Glucocorticoids generally exert a catabolic/antianabolic effect on protein metabolism. Proteolysis in fat, skeletal muscle, bone, lymphoid, and connective tissue increases amino acid substrates that can be used in gluconeogenesis. Cardiac muscle and the diaphragm are almost entirely spared from this catabolic effect.

CIRCULATORY AND RENAL EFFECTS.

Glucocorticoids have a positive inotropic influence on the heart, increasing the left ventricular work index. Moreover, they have a permissive effect on the actions of epinephrine and norepinephrine on both the heart and the blood vessels. In the absence of glucocorticoids, decreased cardiac output and shock may develop; in states of glucocorticoid excess, hypertension is frequently observed. This may be due to activation of the mineralocorticoid receptor (see later), which occurs when renal 11ß-hydroxysteroid dehydrogenase is saturated by excessive levels of glucocorticoids.

GROWTH.

In excess, glucocorticoids inhibit linear growth and skeletal maturation in children. This results primarily from the direct inhibitory effect of glucocorticoids on the epiphyses. This may in part be mediated by decreasing levels of growth hormone and insulin-like growth factor-1 (IGF-1) and by increasing IGF binding protein-1 (IGFBP-1), which inhibits somatic growth by decreasing circulating levels of free IGF-1.

Although excess glucocorticoids clearly impair growth, they are also necessary for normal growth and development. In the fetus and neonate, they accelerate the differentiation and development of various tissues. These actions include the development of the hepatic and gastrointestinal systems, as well as the production of surfactant in the fetal lung. Glucocorticoids are routinely given to pregnant women at risk for delivery of premature infants in an effort to accelerate these maturational processes.

IMMUNOLOGIC EFFECTS.

Glucocorticoids play a major role in immune regulation. They inhibit synthesis of glycolipids and prostaglandin precursors and the actions of bradykinin. They also block histamine and proinflammatory cytokine (tumor necrosis factor-a, interleukin-1, and interleukin-6) secretion and effects. These actions diminish the inflammatory process. High doses of glucocorticoids deplete monocytes, eosinophils, and lymphocytes, especially T cells. They do so at least in part by inducing cell cycle arrest in the G1 phase and by activating apoptosis through glucocorticoid receptor–mediated effects. The effects on lymphocytes are primarily exerted on T

helper 1 cells and hence on cellular immunity, whereas the T helper 2 cells are spared, leading to a predominantly humoral immune response. Pharmacologic doses of glucocorticoids may also decrease the size of immunologic tissues (i.e., the spleen, thymus, and lymph nodes).

Glucocorticoids increase circulating polymorphonuclear cell counts, mostly by preventing their egress from the circulation. Glucocorticoids decrease diapedesis, chemotaxis, and phagocytosis of polymorphonuclear cells. Thus, the mobility of these cells is altered such that they do not arrive at the site of inflammation to mount an appropriate immune response. High levels of glucocorticoids decrease inflammatory and cellular immune responses and increase susceptibility to certain bacterial, viral, fungal, and parasitic infections.

EFFECTS ON SKIN, BONE, AND CALCIUM.

Glucocorticoids inhibit fibroblasts, leading to increased bruising and poor wound healing through cutaneous atrophy. This effect explains the thinning of the skin and striae that are seen in patients with Cushing syndrome.

Glucocorticoids have the overall effect of decreasing serum calcium and have been used in emergency therapy for certain types of hypercalcemia. This hypocalcemic effect probably results from a decrease in the intestinal absorption of calcium and a decrease in the renal reabsorption of calcium and phosphorus. The serum calcium level, however, generally does not fall below normal because of the secondary increase in parathyroid hormone secretion.

The most significant effect of long-term glucocorticoid excess on calcium and bone metabolism is osteoporosis. Glucocorticoids inhibit osteoblastic activity by decreasing the number and activity of osteoblasts. Glucocorticoids also decrease osteoclastic activity, but to a lesser extent, leading to low bone turnover with an overall negative balance. The tendency of glucocorticoids to lower serum calcium and phosphate levels causes secondary hyperparathyroidism. These actions decrease bone accretion and cause a net loss of bone mineral.

CENTRAL NERVOUS SYSTEM EFFECTS.

Glucocorticoids readily penetrate the blood-brain barrier and have direct effects on brain metabolism. They decrease certain types of CNS edema and are frequently used to treat increased intracranial pressure. They stimulate appetite and cause insomnia with a reduction in rapid eye movement sleep. There is an increase in irritability and emotional lability, with an impairment of memory and ability to concentrate. Mild to moderate glucocorticoid excess for a limited period of time often causes a feeling of euphoria or well-being, but glucocorticoid excess and deficiency may both be associated with clinical depression. Furthermore, glucocorticoid excess may produce psychosis in some patients.

Glucocorticoid effects in brain are mediated largely through interactions with both the mineralocorticoid and glucocorticoid receptors (sometimes referred to in this context as type I and type II corticosteroid receptors, respectively). Activation of type II receptors increases sensitivity of hippocampal neurons to the neurotransmitter serotonin, which may help explain the euphoria associated with high doses of glucocorticoids. Glucocorticoids suppress release of corticotropin-releasing hormone (CRH) in the anterior hypothalamus, but stimulate it in the central nucleus of the amygdala and lateral bed nucleus of the stria terminalis, where it may mediate fear and anxiety states. In addition, glucocorticoids and other steroids may have nongenomic effects by modulating activities of both ?-aminobutyric acid (GABA) and *N*-methyl-D-aspartate (NMDA) receptors.

Actions of Mineralocorticoids.

The most important mineralocorticoids are aldosterone and, to a lesser degree, 11-deoxycorticosterone; corticosterone and cortisol are normally not important as mineralocorticoids unless secreted in excess. As a class of hormones, mineralocorticoids have more limited actions than glucocorticoids. Their major function is to maintain intravascular volume by conserving sodium and eliminating potassium and hydrogen ions. They exert these actions in kidney, gut, and salivary and sweat glands. In addition, aldosterone may have distinct effects in other tissues. Mineralocorticoid receptors are found in the heart and vascular endothelium, and aldosterone increases myocardial fibrosis in heart failure.

The distal convoluted tubules and cortical collecting ducts of the kidney are the major sites of action of the mineralocorticoids where they induce reabsorption of sodium and secretion of potassium. In the medullary collecting duct, they act in a permissive fashion to allow vasopressin to increase osmotic water

---

flux. Thus, patients with mineralocorticoid deficiency may develop weight loss, hypotension, hyponatremia, and hyperkalemia, whereas patients with mineralocorticoid excess may develop hypertension, hypokalemia, and metabolic alkalosis (see Chapter 569 , Chapter 570 , Chapter 571 , Chapter 572).

The mechanisms by which aldosterone affects sodium excretion are incompletely understood. Most effects of aldosterone are presumably due to changes in gene expression mediated by the mineralocorticoid receptor, and indeed levels of subunits of both the Na+/K+ ATPase and the epithelial sodium channel (ENaC) increase in response to aldosterone.

The mineralocorticoid receptor has similar affinities in vitro for cortisol and aldosterone, yet cortisol is a weak mineralocorticoid in vivo. This discrepancy results from the action of 11ß-hydroxysteroid dehydrogenase, which converts cortisol to cortisone. Cortisone is not a ligand for the receptor, whereas aldosterone is not a substrate for the enzyme. Pharmacologic or genetic inhibition of this enzyme allows cortisol to occupy renal mineralocorticoid receptors and produce sodium retention and hypertension.

Actions of the Adrenal Androgens.

Many actions of adrenal androgens are exerted through their conversion to active androgens or estrogens such as testosterone, dihydrotestosterone, estrone, and

estradiol. In adult men, less than 2% of the biologically important androgens are derived from adrenal production, whereas in women about 50% of androgens are of adrenal origin. The adrenal contribution to circulating estrogen levels is mainly important in pathologic conditions, such as feminizing adrenal tumors. Adrenal androgens contribute to the physiologic

Figure 568.4-2 Biosynthesis *(above dashed line)* and metabolism *(below dashed line)* of the catecholamines norepinephrine and epinephrine. Enzymes: 1, tyrosine hydroxylase; 2, dopa decarboxylase; 3, dopamine ß-oxidase; 4, phenylethanolamine-*N*-methyltransferase; 5, catechol-O-methyltransferase; 6, monoamine oxidase.

development of pubic and axillary hair during normal puberty. They also play an important role in the pathophysiology of congenital adrenal hyperplasia, premature adrenarche, adrenal tumors, and Cushing syndrome (see Chapter 570 , Chapter 571 , Chapter 573).

In humans, circulating levels of DHEA and DHEAS, the chief adrenal androgens, reach a peak in early adulthood and then decline. This has led to speculation that age-related physiologic changes might be reversed by DHEA administration, and beneficial effects have been proposed on insulin sensitivity, bone mineral density, muscle mass, cardiovascular risk, obesity, cancer risk, autoimmunity, and the central nervous system.

SYNTHETIC CORTICOSTEROIDS.

Many synthetic analogues of cortisone and hydrocortisone are available. Prednisone and prednisolone are derivatives with an additional double bond in ring A. They are 4–5 times as potent in anti-inflammatory and carbohydrate activity but have slightly less effect on retention of water and sodium. Halogenated derivatives have different effects. Betamethasone and dexamethasone have 25–40 times the glucocorticoid potency of cortisol but have little mineralocorticoid effect. These analogues are usually used in pharmacologic doses for their anti-inflammatory or immunosuppressive properties. In contrast, fludrocortisone has about 15 times greater anti-inflammatory activity than does hydrocortisone but is more than 125 times as active a mineralocorticoid; it is used to treat aldosterone deficiency.

568.5 Adrenal Medulla

The principal hormones of the adrenal medulla are the physiologically active catecholamines: dopamine, norepinephrine, and epinephrine (Fig. 568–2). Catecholamine synthesis also occurs in the brain, in sympathetic nerve endings, and in chromaffin tissue outside the adrenal medulla. Metabolites of catecholamines are excreted in the urine. The principal ones are 3-methoxy-4-hydroxymandelic acid (VMA), metanephrine, and normetanephrine. Measurement of metanephrine and catecholamines is used to detect functioning tumors of the adrenal medulla.

The proportions of epinephrine and norepinephrine in the adrenal gland vary with age. In early fetal stages, there is practically no epinephrine; and at birth, norepinephrine is predominant. In adults, norepinephrine makes up only 10–30% of the pressor amines in the medulla.

The effects of catecholamines are mediated through a series of G protein–coupled adrenergic receptors. Both epinephrine and norepinephrine raise the mean arterial blood pressure, but only epinephrine increases cardiac output. By increasing peripheral vascular resistance, norepinephrine increases systolic and diastolic blood pressures with only a slight reduction in the pulse rate. Epinephrine increases the pulse rate and, by decreasing the peripheral vascular resistance, decreases the diastolic pressure. The hyperglycemic and calorigenic effects of norepinephrine are much less pronounced than are those of epinephrine.

Chapter 569 - Adrenocortical Insufficiency

In primary adrenal insufficiency, congenital or acquired lesions of the adrenal cortex prevent production of cortisol and often aldosterone (Box 569–1). Acquired primary adrenal insufficiency is termed *Addison disease*. Dysfunction of the hypothalamus or anterior pituitary gland may cause a deficiency of corticotropin (ACTH) and lead to hypofunction of the adrenal cortex; this is termed *secondary adrenal insufficiency*.

569.1 Primary Adrenal Insufficiency

Primary adrenal insufficiency may be caused by genetic conditions that are not always manifested in infancy and by acquired problems such as autoimmune conditions. However, susceptibility to autoimmune conditions often has a genetic basis, and so these distinctions are not absolute.

Inherited Etiologies

INBORN DEFECTS OF STEROIDOGENESIS.

The most common causes of adrenocortical insufficiency in infancy are the salt-losing forms of congenital adrenal hyperplasia (see Chapter 570). Approximately 75% of infants with 21-hydroxylase deficiency, almost all infants with lipoid adrenal hyperplasia, and most infants with a deficiency of 3ß-hydroxysteroid dehydrogenase manifest salt-losing symptoms in the newborn period because they are unable to synthesize either cortisol or aldosterone.

ADRENAL HYPOPLASIA CONGENITA.

Hypoadrenalism usually presents acutely in the neonatal period but may be delayed until later childhood or even adulthood with a more insidious onset. Histologic examination of the hypoplastic adrenal cortex reveals disorganization and cytomegaly. The disorder affects primarily boys and is caused by mutation of the *DAX1* gene, a member of the nuclear hormone receptor family, located on Xp21. Boys with adrenal hypoplasia congenita (AHC) do not undergo puberty, owing to hypogonadotropic hypogonadism; both AHC and hypogonadotropic hypogonadism are caused by

Box 569.1-1. Etiologic Classification of Adrenocortical Hypofunction

- Corticotropin-releasing hormone deficiency
  - Isolated deficiency
  - Multiple deficiencies
    - Congenital defects (e.g., anencephaly, septo-optic dysplasia)
    - Destructive lesions (e.g., tumor)
    - Idiopathic (e.g., idiopathic hypopituitarism)
- Corticotropin deficiency
  - Isolated
  - Autosomal recessive
  - Multiple deficiencies
    - Pituitary hypoplasia or aplasia
    - Destructive lesions (e.g., craniopharyngioma)
    - Autoimmune hypophysitis
- Primary adrenal hypoplasia or aplasia
  - X-linked
    - With Duchenne muscular dystrophy and glycerol kinase deficiency (Xp21 deletion)
    - With hypogonadotropic hypogonadism (*DAX1* mutation)
- Familial glucocorticoid deficiency
  - Corticotropin-receptor mutations

hypogonadism (*DAX1* mutation)

Familial glucocorticoid deficiency

Corticotropin-receptor mutations

  (ACTH unresponsiveness)
    - With alacrima, achalasia, and neurologic disorders (triple A syndrome)
- Defects of steroid biosynthesis
  - Lipoid adrenal hyperplasia (StAR mutation)
  - 3ß-Hydroxysteroid dehydrogenase deficiency
    - Classic
      - Salt loser
      - Non–salt loser
    - Mild or nonclassic
  - 21-Hydroxylase (P450C21) deficiency
    - Classic
      - Salt loser
      - Non–salt loser
    - Nonclassic or mild
  - Isolated aldosterone (P450C18) deficiency
- Pseudohypoaldosteronism (aldosterone unresponsiveness)
- Adrenoleukodystrophy (peroxisomal membrane protein defect)
  - Isolated adrenal involvement
  - With neurologic involvement
- Acid lipase deficiency
  - Wolman disease, fatal neonatal form
- Destructive lesions of adrenal cortex
  - Granulomatous lesions (e.g.,

Wolman disease, fatal neonatal form

Destructive lesions of adrenal cortex

Granulomatous lesions (e.g., tuberculosis)

Autoimmune adrenalitis (idiopathic Addison disease)

the same mutated *DAX1* gene. Cryptorchidism, often noted in these boys, is probably an early manifestation of hypogonadotropic hypogonadism.

AHC also occurs as part of a contiguous gene deletion syndrome together with Duchenne muscular dystrophy, glycerol kinase deficiency, mental retardation, or a combination of these conditions.

ADRENOLEUKODYSTROPHY.

In this disorder, adrenocortical deficiency is associated with demyelination in the central nervous system (see Chapters 75.2 and 592.3). High levels of very long-chain fatty acids are found in tissues and body fluids, resulting from their impaired ß-oxidation in the peroxisomes.

The most frequent form of ALD is an X-linked disorder with various presentations. The most common clinical picture is of a degenerative neurologic disorder appearing in childhood or adolescence and progressing to severe dementia and deterioration of vision, hearing, speech, and gait, with death occurring within a few years. A milder form of X-linked ALD is adrenomyeloneuropathy (ALM), which begins in later adolescence or early adulthood. Many patients have evidence of adrenal insufficiency at the time of neurologic presentation, but Addison disease may precede neurologic symptoms by many years. X-linked ALD may present as isolated Addison disease. X-linked adrenal leukodystrophy (X-ALD) is caused by mutations in the *ABCD1* gene located on Xq28. The gene encodes a transmembrane transporter involved in the importation of very long-chain fatty acids into peroxisomes. More than 400 mutations have been described in patients with X-ALD; the majority of X-ALD families have a unique mutation. Clinical phenotypes can vary even within families, perhaps owing to modifier genes or other unknown factors. There is no correlation between the degree of neurologic impairment and severity of adrenal insufficiency. Prenatal diagnosis by DNA analysis and family screening by very long-chain fatty acids assays and mutation analysis are available. Women who are heterozygous carriers of the *X-ALD* gene may develop symptoms in midlife or later. Adrenal insufficiency is rare. Therapeutic approaches of uncertain efficacy include administration of glycerol trioleate and glycerol trierucate (Lorenzo's oil), bone marrow transplantation, lovastatin, fenofibrate, and gene therapy.

Neonatal ALD is a rare autosomal recessive disorder. Infants present with neurologic deterioration and have or acquire evidence of adrenocortical dysfunction. Most patients have severe mental retardation and die before 5 yr of age. This disorder is a subset of Zellweger (cerebro-hepato-renal) syndrome, in which peroxisomes do not develop at all owing to mutations in any of several genes controlling the development of this organelle.

FAMILIAL GLUCOCORTICOID DEFICIENCY.

This form of chronic adrenal insufficiency is characterized by isolated deficiency of glucocorticoids, elevated levels of ACTH, and normal aldosterone production. The salt-losing manifestations present in most other forms of adrenal insufficiency do not occur; instead, patients present primarily with hypoglycemia, seizures, and increased pigmentation during the 1st decade of life. The disorder affects both sexes equally and is inherited in an autosomal recessive manner. There is marked adrenocortical atrophy with relative sparing of the zona glomerulosa. A number of mutations in the gene for the ACTH receptor have been described in some (approximately 40%) but not all of these patients.

Another syndrome of ACTH resistance occurs in association with achalasia of the gastric cardia and alacrima (triple A or Allgrove syndrome). These patients often have a progressive neurologic disorder that includes autonomic dysfunction, mental retardation, deafness, and motor neuropathy. This syndrome is also inherited in an autosomal recessive fashion, and the gene has been mapped to chromosome 12q13.

DISORDERS OF CHOLESTEROL SYNTHESIS/METABOLISM.

Patients with disorders of cholesterol synthesis or metabolism, including abetalipoproteinemia with deficient lipoprotein B–containing lipoproteins, and familial hypercholesterolemia, with decreased or impaired LDL receptors, have been demonstrated to have limited adrenal cortical function. Adrenal insufficiency has been reported in patients with Smith-Lemli-Opitz syndrome (SLOS), an autosomal recessive disorder presenting with facial anomalies, microcephaly, limb anomalies, and developmental delay. Mutations in the gene coding for sterol ?7-reductase, mapped to 11q12-q13, resulting in impairment of

---

the final step in cholesterol synthesis with marked elevation of 7-dehydrocholesterol, abnormally low cholesterol, and adrenal insufficiency have been identified in SLOS. Wolman disease is a rare autosomal recessive disorder caused by mutations in the gene encoding human lysosomal acid lipase. There is marked intralysosomal accumulation of cholesterol esters throughout most organ systems and ultimately organ failure. Infants present during the first or second month of life with hepatosplenomegaly, steatorrhea, abdominal distention, and failure to thrive. Adrenal insufficiency and bilateral adrenal calcification are present and death usually occurs in the first year of life. The gene for lysosomal acid lipase has been mapped to chromosome 10q23.2-23.3; the genetic defects in patients with Wolman disease have been elucidated.

CORTICOSTEROID BINDING GLOBULIN (CBG) DEFICIENCY AND DECREASED CORTISOL-BINDING AFFINITY.

These disorders result in low levels of plasma cortisol but normal urinary free cortisol and normal plasma ACTH levels. A high prevalence of hypotension and fatigue has been reported in some adults with abnormalities of CBG.

Acquired Etiologies

AUTOIMMUNE ADDISON DISEASE.

The most common cause of Addison disease is autoimmune destruction of the glands. The glands may be so small that they are not visible at autopsy, and only remnants of tissue are found in microscopic sections. Usually the medulla is not destroyed, and there is marked lymphocytic infiltration in the area of the former cortex. In advanced disease, all adrenal cortical function is lost, but early in the clinical course, isolated cortisol deficiency may occur. Most patients have antiadrenal cytoplasmic antibodies in their plasma; 21-hydroxylase (CYP21) is the most frequently occurring autoantigen.

Addison disease often occurs as a component of two syndromes, each consisting of a constellation of autoimmune disorders. *Type I autoimmune polyendocrinopathy* (APS-1) is also known as the *autoimmune polyendocrinopathy/candidiasis/ectodermal dystrophy* (APECED) syndrome. Chronic mucocutaneous candidiasis is most often the first manifestation, followed by hypoparathyroidism and then by Addison disease, which typically develops in early adolescence. Other closely associated autoimmune disorders include gonadal failure, alopecia, vitiligo, keratopathy, enamel hypoplasia, nail dystrophy, intestinal malabsorption, and chronic active hepatitis. Hypothyroidism and type I diabetes mellitus occur in fewer than 10% of affected patients. Some components of the syndrome continue to develop as late as the 5th decade. The presence of antiadrenal antibodies and steroidal cell antibodies in these patients usually indicates a high likelihood of the development of Addison disease or, in females, ovarian failure. Adrenal failure may evolve rapidly in APS-1; death in patients previously diagnosed and unexplained deaths in siblings of patients with APS-1 have been reported, indicating the need to closely monitor patients with APS-1 and to thoroughly evaluate apparently unaffected siblings of patients with this disorder.

Autoantibodies to the CYP21, CYP17, and CYP11A1 enzymes have been reported in patients with APS-1. The disorder is inherited as an autosomal recessive disorder, and the gene, designated autoimmune regulator-1 (AIRE1), has been mapped to chromosome 21q22.3. The *AIRE1* gene encodes a protein, which appears to be a transcription factor having an important role in immune response. Approximately 40 different mutations in the *AIRE1* gene have been described in patients with APS-1, with two mutations (R257X and a 3-bp deletion) being most frequent. There has been autosomal dominant transmission in one kindred owing to a specific missense mutation (G228W).

Type II autoimmune polyendocrinopathy (APS-2) consists of Addison disease associated with autoimmune thyroid disease (Schmidt syndrome) or type-1 diabetes (Carpenter syndrome). Gonadal failure, vitiligo, alopecia, and chronic atrophic gastritis, with or without pernicious anemia, may occur. HLA-D3 and HLA-D4 are increased in these patients and appear to confer an increased risk of developing this disease; alleles at the major histocompatibility complex class I chain-related genes A and B (MICA and MICB) have also been associated with this disorder. The disorder is most common in middle-aged females and may occur in many generations of the same family. Antiadrenal antibodies, specifically antibodies to the CYP21, CYP17,

and CYP11A1 enzymes, are also found in these patients.

INFECTION.

Tuberculosis was a common cause of adrenal destruction in the past but is much less prevalent now. The most frequent infectious etiology for adrenal insufficiency is meningococcemia (see Chapter 176); adrenal crisis from this cause is referred to as the Waterhouse-Friderichsen syndrome. Patients with AIDS may have a variety of subclinical abnormalities in the hypothalamic-pituitary-adrenal axis, but frank adrenal insufficiency is rare. However, drugs used in the treatment of AIDS may affect adrenal hormone homeostasis.

DRUGS.

Ketoconazole, an antifungal drug, can cause adrenal insufficiency by inhibiting adrenal enzymes. Rifampicin and anticonvulsive drugs such as phenytoin and phenobarbital reduce the effectiveness and bioavailability of corticosteroid replacement therapy by inducing steroid-metabolizing enzymes in the liver. Mitotane (o,p'-DDD), used in the treatment of adrenal carcinoma and refractory Cushing syndrome (see Chapters 571 , 573), is cytotoxic to the adrenal cortex and may also alter extra-adrenal cortisol metabolism. Signs of adrenal insufficiency occur in a substantial percentage of patients treated with mitotane.

HEMORRHAGE INTO ADRENAL GLANDS.

This may occur in the neonatal period as a consequence of difficult labor (especially breech presentation), or its etiology may not be apparent. An incidence rate of 3 per 100,000 live births has been suggested. The hemorrhage may be sufficiently extensive to result in death from exsanguination or hypoadrenalism. An abdominal mass, anemia, unexplained jaundice, or scrotal hematoma may be the presenting sign. Often, the hemorrhage is asymptomatic initially and is identified later by calcification of the adrenal gland. Fetal adrenal hemorrhage has also been reported. Postnatally, adrenal hemorrhage most often occurs in patients being treated with anticoagulants. It may also occur as a result of child abuse.

Clinical Manifestations.

Primary adrenal insufficiency leads to cortisol and often aldosterone deficiency. The signs and symptoms of adrenal insufficiency are most easily understood in the context of the normal actions of these hormones, which were discussed in Chapter 568 .

Hypoglycemia is a prominent feature of adrenal insufficiency. It is often accompanied by ketosis as the body attempts to utilize fatty acids as an alternative energy source. It is aggravated by anorexia, nausea, and vomiting, all of which occur frequently.

Cortisol deficiency decreases cardiac output and vascular tone; moreover, catecholamines such as epinephrine have decreased inotropic and pressor effects in the absence of cortisol. These problems are initially manifested as orthostatic hypotension in older children and may progress to frank shock in patients of any age. They are exacerbated by aldosterone deficiency, which results in hypovolemia due to decreased resorption of sodium in the distal nephron.

Hypotension and decreased cardiac output decrease glomerular filtration and thus decrease the ability of the kidney to excrete free water. Vasopressin (AVP) is secreted by the posterior pituitary in response to hypotension and also as a direct consequence of lack of inhibition by cortisol. These factors decrease plasma osmolality and lead in particular to hyponatremia. Hyponatremia is also caused by aldosterone deficiency and may be much worse when both cortisol and aldosterone are deficient.

In addition to hypovolemia and hyponatremia, aldosterone deficiency causes hyperkalemia by decreasing potassium excretion

---

in the distal nephron. However, cortisol deficiency alone does not cause hyperkalemia.

Finally, cortisol deficiency decreases negative feedback on the hypothalamus and pituitary, leading to increased secretion of ACTH. Hyperpigmentation is caused by ACTH and other peptide hormones (e.g., ?-melanocyte stimulating hormone) arising from the ACTH precursor pro-opiomelanocortin. In patients with a fair complexion, the skin may have a bronze cast. Pigmentation may be more prominent in skin creases, mucosa, and scars. In dark-skinned patients, it may be most readily appreciated in the gingival and buccal mucosa.

The clinical presentation of adrenal insufficiency depends on the age of the patient, whether both cortisol and aldosterone secretion are affected, and to some extent on the underlying etiology. The most common causes in early infancy are inborn errors of steroid biosynthesis, sepsis, adrenal hypoplasia congenita, and adrenal hemorrhage. Infants have a relatively greater requirement for aldosterone than older children, possibly owing to immaturity of the kidney and also to the low sodium content of human breast milk and infant formula. Hyperkalemia, hyponatremia, and hypoglycemia are prominent presenting signs of adrenal insufficiency in infants. Ketosis is not consistently present because infants generate ketones less well than older children. Hyperpigmentation is not usually seen because this takes weeks or months to develop, and orthostatic hypotension is obviously difficult to demonstrate in infants.

Infants can become ill very quickly. There may be only a few days of decreased activity, anorexia, and vomiting before critical electrolyte abnormalities develop.

In older children with Addison disease, the onset is usually more gradual and is characterized by muscle weakness, malaise, anorexia, vomiting, weight loss, and orthostatic hypotension. Hyperpigmentation is often but not necessarily present. Hypoglycemia and ketosis are common, as is hyponatremia. Hyperkalemia tends to occur later in the course of the disease in older children than in infants. Thus, the clinical presentation can be easily confused with gastroenteritis or other acute infections. Chronicity of symptoms may alert the clinician to the possibility of Addison

disease, but this diagnosis should be considered in any child with orthostatic hypotension, hyponatremia, hypoglycemia, and ketosis.

Laboratory Findings.

Hypoglycemia, ketosis, hyponatremia, and hyperkalemia have been discussed. An electrocardiogram is useful for quickly detecting hyperkalemia in a critically ill child. Acidosis is frequently present, and the blood urea nitrogen level is elevated if the patient is dehydrated.

Cortisol levels may sometimes be at the low end of the normal range but are invariably low when the patient's degree of illness is considered. ACTH levels are high in primary adrenal insufficiency but may take time to be reported by the laboratory. Similarly, aldosterone levels may be within the normal range but inappropriately low considering the patient's hyponatremia, hyperkalemia, and hypovolemia. Plasma renin activity is elevated. Blood eosinophils may be increased in number, but this is rarely useful diagnostically.

Urinary excretion of sodium and chloride are increased and urinary potassium is decreased, but these are difficult to assess on random urine samples. Accurate interpretation of urinary electrolytes requires more prolonged (24?hr) urine collections and knowledge of the patient's sodium and potassium intake.

The most definitive test for adrenal insufficiency is measurement of serum levels of cortisol before and after administration of ACTH; resting levels are low and do not increase normally after administration of ACTH. Occasionally, normal resting levels that do not increase after administration of ACTH may indicate an absence of adrenocortical reserve. A low initial level followed by a significant response to ACTH may indicate secondary adrenal insufficiency. Traditionally, this test has been performed by measuring cortisol levels before and 30 or 60 minutes after giving 0.250?mg of cosyntropin (ACTH 1-24) by rapid intravenous infusion. Aldosterone will transiently increase in response to this dose of ACTH and may also be measured. A low-dose test (0.5–1?µg ACTH 1–24/1.73?m^2) is a more sensitive test of pituitary-adrenal reserve but has somewhat lower specificity (i.e., more false-positive tests).

Additional testing is directed at identifying the specific cause for adrenal insufficiency. When congenital adrenal hyperplasia is suspected, serum levels of cortisol precursors (e.g., 17-hydroxyprogesterone) should be measured along with cortisol in an ACTH stimulation test. This is discussed further in Chapter 570 . Elevated levels of very long-chain fatty acids are diagnostic of adrenoleukodystrophy. The presence of antiadrenal antibodies suggests an autoimmune pathogenesis. Patients with autoimmune Addison disease must be closely observed for the development of other autoimmune disorders. In children, hypoparathyroidism is the most frequently associated disorder, and is suspected if hypocalcemia and elevated phosphate levels are noted.

Ultrasonography, CT, or MRI may help define the size of the adrenal glands.

Treatment.

Treatment of acute adrenal insufficiency must be immediate and vigorous. If the diagnosis of adrenal insufficiency has not been established, a blood sample should be obtained before therapy for determination of electrolytes, glucose, ACTH, cortisol, aldosterone, and plasma renin activity. If the patient's condition permits, an ACTH stimulation test can be performed while initial fluid resuscitation is underway. Intravenous administration of 5% glucose in 0.9% saline solution should be given to correct hypoglycemia, hypovolemia, and hyponatremia. If hyperkalemia is severe, it may require treatment with intravenous calcium and/or bicarbonate, intrarectal potassium-binding resin (Kayexalate), or intravenous infusion of glucose and insulin. A water-soluble form of hydrocortisone, such as hydrocortisone sodium succinate, should be given intravenously. As much as 10?mg for infants, 25?mg for toddlers, 50?mg for older children, and 100?mg for adolescents should be administered at 6-hr intervals for the first 24?hr. These doses may be reduced during the next 24?hr if progress is satisfactory. Adequate fluid and sodium repletion is achieved by intravenous saline administration, aided by the mineralocorticoid effect of high doses of hydrocortisone.

After the acute manifestations are under control, most patients require chronic replacement therapy for their cortisol and aldosterone deficiencies. Hydrocortisone (i.e., cortisol) may be given orally in daily doses of 10?mg/M^2 /24?hr in three divided doses. Equivalent doses (20–25% of the hydrocortisone dose) of prednisone or prednisolone may be used, divided twice daily. ACTH levels may be used to monitor adequacy of glucocorticoid replacement in primary adrenal insufficiency; in congenital adrenal hyperplasia, levels of precursor hormones are used instead (see Chapter 570). During situations of stress, such as periods of infection or minor operative procedures, the dose of hydrocortisone should be increased 2–3 fold. Major surgery under general anesthesia requires high intravenous doses of hydrocortisone similar to those used for acute adrenal insufficiency. If aldosterone deficiency is present, fludrocortisone (Florinef), a mineralocorticoid, is given orally in doses of 0.05–0.3?mg daily. Measurements of plasma renin activity are useful in monitoring the adequacy of mineralocorticoid replacement. Chronic overdosage with glucocorticoids leads to obesity, short stature, and osteoporosis, whereas overdosage with fludrocortisone results in tachycardia, hypertension, and occasionally hypokalemia.

569.2 Secondary Adrenal Insufficiency

Etiology

ABRUPT CESSATION OF ADMINISTRATION OF CORTICOSTEROIDS.

Secondary adrenal insufficiency most commonly occurs when the hypothalamic-pituitary-adrenal axis is suppressed by prolonged administration of high doses of a potent glucocorticoid and that agent is suddenly withdrawn or the dose is tapered too quickly. Patients at risk for this problem include those with leukemia, asthma (particularly when patients are transitioned from oral to inhaled corticosteroids), and collagen vascular disease or other autoimmune conditions and

those who have undergone tissue transplants or neurosurgical procedures. The maximum duration and dose of glucocorticoid that can be administered before encountering this problem is not known, but it is assumed that high dose glucocorticoids (the equivalent of >10 times physiologic cortisol secretion) can be administered for at least a week without requiring a subsequent taper of dose. On the other hand, when high doses of dexamethasone are given to children with leukemia, it can take up to 2 mo or longer after therapy is stopped before tests of adrenal function return to normal. Signs and symptoms of adrenal insufficiency are most likely in patients who are subsequently subjected to stresses such as severe infections or additional surgical procedures.

CORTICOTROPIN (ACTH) DEFICIENCY.

Pituitary or hypothalamic dysfunction can cause corticotropin deficiency (see Chapter 557), usually associated with deficiencies of other pituitary hormones such as growth hormone and thyrotropin. Destructive lesions in the area of the pituitary, such as craniopharyngioma and germinoma, are the most common causes of corticotropin deficiency. In many cases the pituitary or hypothalamus are further damaged during surgical removal or radiotherapy of tumors in the midline of the brain. In very rare instances, autoimmune hypophysitis has been the cause of corticotropin deficiency.

Congenital lesions of the pituitary also occur. The pituitary alone may be affected, or additional midline structures may be involved, such as the optic nerves or septum pellucidum. The latter type of abnormality is termed *septo-optic dysplasia* or *de Morsier syndrome.* More severe developmental anomalies of the brain, such as anencephaly and holoprosencephaly, can also affect the pituitary. These disorders are usually sporadic, although a few cases of autosomal recessive inheritance have occurred. Isolated deficiency of corticotropin has been reported, including in several sets of siblings. Patients with multiple pituitary hormone deficiencies due to mutations in the *PROP1* gene have been described with progressive ACTH/cortisol deficiency. Isolated deficiency of corticotropin-releasing hormone has been documented in an Arabic kindred as an autosomal recessive trait.

Clinical Presentation.

Because the adrenal gland is, by definition, intact in secondary adrenal insufficiency, and the renin-angiotensin system is not involved, aldosterone secretion is unaffected. Thus, signs and symptoms are those of cortisol deficiency. Newborns often present with hypoglycemia. Older children may have orthostatic hypotension or weakness. Electrolytes are usually normal.

When secondary adrenal insufficiency is due to an inborn or acquired anatomic defect involving the pituitary, there may be signs of associated deficiencies of other pituitary hormones. The penis may be small in male infants if gonadotropins are also deficient. Infants with secondary hypothyroidism are often jaundiced. Children with associated growth hormone deficiency grow poorly after the 1st yr of life.

Some children with pituitary abnormalities have hypoplasia of the midface. Children with optic nerve hypoplasia may have obvious visual impairment. They usually have a characteristic wandering nystagmus, but this is often not apparent until several months of age.

Treatment.

Iatrogenic secondary adrenal insufficiency (i.e., caused by chronic glucocorticoid administration) is best avoided by using the smallest effective doses of systemic glucocorticoids for the shortest period of time. When a patient is thought to be at risk, tapering the dose rapidly to a level equivalent to or slightly less than physiologic replacement (~10?mg/M^2 /24h) and further tapering over several weeks may allow the adrenal cortex to recover without signs of adrenal insufficiency developing. Patients with anatomic lesions of the pituitary should be treated indefinitely with glucocorticoids. Mineralocorticoid replacement is not required.

Chapter 570 - Congenital Adrenal Hyperplasia and Related Disorders

Congenital adrenal hyperplasia (CAH) is a family of autosomal recessive disorders of cortisol biosynthesis (normal adrenal steroidogenesis is discussed in Chapter 568). Cortisol deficiency increases secretion of corticotropin (ACTH), which in turn leads to adrenocortical hyperplasia and overproduction of intermediate metabolites. Depending on the enzymatic step that is deficient, there may be signs, symptoms, and laboratory findings of mineralocorticoid deficiency or excess; incomplete virilization or premature puberty in affected males; and virilization or sexual infantilism in affected females (Figs. 570–1 and 570–2 ; Table 570–1).

570.1 Congenital Adrenal Hyperplasia due to 21-Hydroxylase Deficiency

More than 90% of CAH cases are caused by 21-hydroxylase deficiency. This P450 enzyme (CYP21, P450c21) hydroxylates progesterone and 17-hydroxyprogesterone (17-OHP) to yield 11-deoxycorticosterone (DOC) and 11-deoxycortisol, respectively (see Fig. 568–1). These conversions are required for synthesis of aldosterone and cortisol, respectively. Both hormones are deficient in the most severe, “salt wasting” form of the disease. Slightly less severely affected patients are able to synthesize adequate amounts of aldosterone but have elevated levels of androgens of adrenal origin; this is termed *simple virilizing* disease. These two forms are collectively termed *classic* 21-hydroxylase deficiency. Patients with *nonclassic* disease have relatively mildly elevated levels of androgens and may have signs of androgen excess postnatally.

Classic 21-hydroxylase deficiency occurs in about 1 in 15,000–20,000 births in most populations. Approximately 75% of affected infants have the salt-losing form, whereas 25% have the simple virilizing form of the disorder. Nonclassic disease has a prevalence of about 1/1,000 in the general population but occurs more frequently in specific ethnic groups such as Ashkenazi Jews.

Genetics.

There are two steroid 21-hydroxylase genes, *CYP21P (CYP21A1P, CYP21A)* and *CYP21 (CYP21A2, CYP21B),* which alternate in tandem with two genes for the fourth component of complement *(C4A* and *C4B)* in the human leukocyte antigen major histocompatibility complex on chromosome 6p21.3 between the HLA-B and HLA-DR loci. Many other genes are located in this cluster. *CYP21* is the active gene; *CYP21P* is 98% identical in DNA sequence to *CYP21* but is a pseudogene due to nine different mutations. More than 90% of mutations causing 21-hydroxylase deficiency are recombinations between *CYP21* and *CYP21P.* Approximately 20% are deletions generated by unequal meiotic crossing-over between *CYP21* and *CYP21P,* whereas the remainder are nonreciprocal transfers of deleterious mutations from *CYP21P* to *CYP21,* a phenomenon termed *gene conversion.*

The deleterious mutations in *CYP21P* have varying effects on enzymatic activity when transferred to *CYP21.* Several mutations completely prevent synthesis of a functional protein, whereas others are missense mutations (i.e., they result in amino acid substitutions) that yield enzymes with 1–50% of normal activity. Disease severity correlates well with the mutations carried by an affected individual; for example, patients with salt-wasting disease usually carry mutations on both alleles that completely destroy enzymatic activity. When patients are compound heterozygotes for different types of mutations, the severity of disease expression is largely determined by the activity of the less severely affected of the two alleles.

Clinical Manifestations

ALDOSTERONE AND CORTISOL DEFICIENCY.

Because both cortisol and aldosterone require 21-hydroxylation for their synthesis, both hormones are deficient in the most severe, “salt wasting” form of the disease. This form constitutes about 75% of cases of classic 21-hydroxylase deficiency. The signs and symptoms of cortisol and aldosterone deficiency, and the pathophysiology underlying them, are essentially those described in Chapter 569 . These include progressive weight loss, anorexia, vomiting, dehydration, weakness, hypotension, hypoglycemia, hyponatremia and hyperkalemia. These problems typically first develop in affected infants at approximately 2 wk of age. Without treatment, shock, cardiac arrhythmias, and death may occur within days or weeks.

CAH differs from other causes of primary adrenal insufficiency in that precursor steroids accumulate proximal to the blocked enzymatic conversion. Because cortisol is not synthesized efficiently, ACTH levels are high, leading to hyperplasia of the adrenal cortex and levels of precursor steroids that may be hundreds of times normal. In the case of 21-hydroxylase deficiency, these precursors include 17-hydroxyprogesterone and progesterone. Progesterone and perhaps other metabolites act as antagonists of the mineralocorticoid receptor and thus may exacerbate the effects of aldosterone deficiency in untreated patients.

PRENATAL ANDROGEN EXCESS.

The most important problem caused by accumulation of steroid precursors is that 17-hydroxyprogesterone is shunted into the pathway for androgen biosynthesis, leading to high levels of androstenedione that are converted outside the adrenal gland to testosterone. This problem begins in affected fetuses by 8–10 wk of gestation and leads to abnormal genital development in females (see Figs. 570–1 and 570–2).

The external genitalia of males and females normally appear identical early in gestation (see Chapter 576). In normal females, the genital tubercle becomes the clitoris; the urethral folds develop into the labia minora, and the labioscrotal swellings become the labia majora. In males, development of the external genitalia is normally controlled by testosterone secreted by the fetal testes. The genital tubercle enlarges to become the glans of the penis; the urethral folds fuse to form the shaft of the penis and penile urethra, and the labioscrotal swellings fuse to form the scrotum. Testosterone also controls the development of the wolffian ducts into male internal genital structures such as the prostate, spermatic ducts, and epididymis, but higher levels of testosterone are required than for development of the male external genitalia. In contrast, testosterone has no effect on development of female internal reproductive structures (cervix, uterus, and fallopian tubes) from müllerian ducts. In male fetuses, these structures involute under the influence of anti-müllerian hormone (müllerian inhibitory factor) secreted by the testes.

Thus, affected females, who are exposed in utero to high levels of androgens of adrenal origin, have masculinized external genitalia. This is manifested by enlargement of the clitoris and by partial or complete labial fusion. The vagina usually has a common opening with the urethra (urogenital sinus). The clitoris may be so enlarged that it resembles a penis and, because the urethra opens below this organ, some affected females may be mistakenly presumed to be males with hypospadias and cryptorchidism. The severity of virilization is greatest in females with the salt-losing form of 21-hydroxylase deficiency. The internal genital organs are normal, because affected females

Figure 570.1-1 *A,* A 6-yr-old girl with congenital virilizing adrenal hyperplasia. The height age was 8.5 yr; the bone age was 13 yr; and urinary 17-ketosteroids were 50?mg/24?hr. *B,* Notice the clitoral enlargement and labial fusion. *C,* Five-yr-old brother of girl in *A* was not considered to be abnormal by the parents. The height age was 8 yr; the bone age was 12.5 yr; and the urinary 17-ketosteroids were 36?mg/24?hr.

have normal ovaries and not testes and thus do not secrete anti- müllerian hormone.

Prenatal exposure of the brain to high levels of androgens may influence subsequent sexually dimorphic behaviors in affected females. Girls tend to be interested in masculine toys such as cars and trucks and often show decreased interest in playing with dolls. Women may have decreased interest in maternal roles. There is an increased frequency of homosexuality in affected females, but most function heterosexually. It is unusual for affected females to assign themselves a male role.

Male infants appear normal at birth. Thus, the diagnosis may not be made in boys until signs of adrenal insufficiency develop. Because patients with this condition can deteriorate quickly,

Figure 570.1-2 Three female pseudohermaphrodites with untreated congenital adrenal hyperplasia. All were erroneously assigned male sex at birth, and each had normal female sex-chromosome complement. Infants *A* and *B* were salt losers and were diagnosed in early infancy. Infant *C* was referred at 1 yr of age because of bilateral cryptorchidism. Notice the completely penile urethra; such complete degrees of masculinization in females with adrenal hyperplasia are rare; most of these infants are salt losers.

infant boys are much more likely to die than girls. For this reason, many states and countries have instituted newborn screening for this condition (see later).

POSTNATAL ANDROGEN EXCESS.

Untreated or inadequately treated children of both sexes develop additional signs of androgen excess after birth. Boys with the simple virilizing form of 21-hydroxylase deficiency often have delayed diagnosis because they appear normal and rarely develop adrenal insufficiency.

Signs of androgen excess include rapid somatic growth and accelerated skeletal maturation. Thus, affected patients are tall in childhood but premature closure of the epiphyses causes growth to stop relatively early, and adult stature is stunted (see Fig. 570–1). Muscular development may be excessive. Pubic and

TABLE 570.1-1 -- **Diagnosis and Treatment of Congenital Adrenal Hyperplasia**

Disorder	Signs and Symptoms	Laboratory Findings	Therapeutic Measures
Lipoid congenital adrenal hyperplasia	Salt-wasting crisis	Low levels of all steroid hormones, with decreased or absent response to ACTH	Glucocorticoid and mineralocorticoid administration
	Male pseudohermaphoditism		
		Decreased or absent response to hCG in male pseudohermaphroditism	Sodium chloride supplementation
			Gonadectomy of male pseudohermaphrodite
		? ACTH	Sex hormone replacement consonant with sex of rearing
		? PRA	
3ß-HSD deficiency	Classic form:	??Baseline and ACTH-stimulated ?5 steroids (pregnenolone, 17-OH pregnenolone, DHEA, and their urinary metabolites)	Glucocorticoid and mineralocorticoid administration

	Salt-wasting crisis		
	Male and female pseudohermaphroditism		Sodium chloride supplementation
		? ACTH	Surgical correction of genitals and sex hormone replacement as necessary consonant with sex of rearing
	Precocious pubarche	? PRA	
	Disordered puberty	Suppression of elevated adrenal steroids after glucocorticoid administration	
3ß-HSD deficiency	Nonclassic form:	? Baseline and ACTH-stimulated ?5 steroids (pregnenolone, 17-OH pregnenolone, DHEA, and their urinary metabolites)	Glucocorticoid administration
	Precocious pubarche, disordered puberty, menstrual irregularity, hirsutism, acne, infertility		
		? ?5/?4 serum and urinary steroids	
		Suppression of elevated adrenal steroids after glucocorticoid administration	
21-OH deficiency	Classic form:	? ? Baseline and ACTH-stimulated	Glucocorticoid and mineralocorticoid replacement
	Salt-wasting crisis	17-OH progesterone and pregnanetriol	
	Female pseudohermaphroditism	? ? Serum androgens and urinary metabolites	Sodium chloride supplementation
	Postnatal virilization		Vaginoplasty and clitoral recession in female pseudohermaphroditism
		? ACTH	
		? PRA	
		Suppression of elevated adrenal steroids after glucocorticoid administration	
21-OH deficiency	Nonclassic form:	? Baseline and ACTH-stimulated 17-OH progesterone and pregnanetriol	Glucocorticoid administration
	Precocious pubarche, disordered puberty, menstrual irregularity, hirsutism, acne, infertility		
		? Serum androgens and urinary metabolities	
		Suppression of elevated adrenal steroids after glucocorticoid administration	
11ß-Hydroxylase deficiency	Classic form:	? ? Baseline and ACTH-stimulated compound S and DOC and their urinary metabolites	Glucocorticoid administration
	Female pseudohermaphroditism		Vaginoplasty and clitoral recession in female pseudohermaphroditism
	Postnatal virilization in males and females	? ? Serum androgens and their urinary metabolites	
	Hypertension	? ACTH	
		? PRA	
		Hypokalemia	
		Suppression of elevated steroids after glucocorticoid administration	
11ß-Hydroxylase deficiency	Nonclassic form:	? Baseline and ACTH-stimulated compound S and DOC and their urinary metabolites	Glucocorticoid administration

	Precocious pubarche, disordered puberty, menstrual irregularity, hirsutism, acne, infertility	? Serum androgens and their urinary metabolites	
		Suppression of elevated steroids after glucocorticoid administration	
17a-OH/17,20-lyase deficiency	Male pseudohermaphroditism	? ? DOC, 18-OH DOC, corticosterone, 18-hydroxycorticosterone	Glucocorticoid administration
	Sexual infantilism		Surgical correction of genitals and sex hormone replacement in male pseudohermaphroditism consonant with sex of rearing
	Hypertension	Low 17-a-hydroxylated steroids and poor response to ACTH	
		Poor response to hCG in male pseudohermaphroditism	Sex hormone replacement in female
		? PRA	
		? ACTH	
		Hypokalemia	
		Suppression of elevated adrenal steroids after glucocorticoid administration	

ACTH = adrenocorticotropic hormone (corticotropin); hCG = human chorionic gonadotropin; PRA = plasma renin activity; DOC = deoxycorticosterone. Adapted from Miller WL, Levine LS: Molecular and clinical advances in congenital adrenal hyperplasia. J Pediatr *1987;111:1.*

axillary hair may appear; and acne and a deep voice may develop. The penis, scrotum, and prostate may become enlarged in affected boys; however, the testes are usually prepubertal in size so that they appear relatively small in contrast to the enlarged penis. Occasionally, ectopic adrenocortical cells in the testes of patients become hyperplastic similar to the adrenal glands, producing testicular adrenal rest tumors (see Chapter 578). The clitoris may become further enlarged in affected females (see Fig. 570–1). Although the internal genital structures are female, breast development and menstruation do not occur unless the excessive production of androgens is suppressed by adequate treatment.

Similar but milder signs of androgen excess may occur in nonclassic 21-hydroxylase deficiency. In this attenuated form, cortisol and aldosterone levels are normal and affected females have normal genitalia at birth. Males and females may present with precocious pubarche and early development of pubic and axillary hair. Hirsutism, acne, menstrual disorders, and infertility may develop later in life. However, many females and males are completely asymptomatic.

Laboratory Findings (see Table 570–1).

Patients with salt-losing disease have typical laboratory findings associated with cortisol and aldosterone deficiency, including hyponatremia, hyperkalemia,

acidosis, and often hypoglycemia, but these abnormalities can take 1–2 wk or longer to develop after birth. Blood levels of 17-hydroxyprogesterone are markedly elevated. However, levels of this hormone are high during the first 2–3 days of life, even in unaffected infants and especially if they are sick or premature. After infancy, once the circadian rhythm of cortisol is established, 17-hydroxyprogesterone levels vary in the same circadian pattern, being highest in the morning and lowest at night. Blood levels of cortisol are usually low in patients with the salt-losing type of disease. They are often normal in those with the simple virilizing type but inappropriately low in relation to the ACTH and 17-hydroxyprogesterone levels. In addition to 17-hydroxyprogesterone, levels of androstenedione and testosterone are elevated in affected females; testosterone is not elevated in affected males because normal infant males have high testosterone levels compared with those seen later in childhood. Levels of urinary 17-ketosteroids and pregnanetriol are elevated but are now rarely used clinically because blood samples are easier to obtain than 24-hr urine collections. Corticotropin (ACTH) levels are elevated but have no diagnostic utility over 17-hydroxyprogesterone levels. Plasma levels of renin are elevated, and serum aldosterone is inappropriately low for the renin level. However, renin levels are normally high in the first few days of life.

Diagnosis of 21-hydroxylase deficiency is most reliably established by measuring 17-hydroxyprogesterone before and 30 or 60?min after an intravenous bolus of 0.125–0.25?mg of cosyntropin (ACTH 1–24). Nomograms exist that readily distinguish normals and patients with nonclassic and classic 21-hydroxylase deficiency. Heterozygous carriers of this autosomal recessive disorder tend to have higher ACTH-stimulated 17-hydroxyprogesterone levels than genetically unaffected individuals, but there is significant overlap between subjects in these two categories.

ADDITIONAL STUDIES.

Intersex conditions are discussed more generally in Chapter 582 . The initial step in evaluating an infant with ambiguous genitalia is a thorough physical examination to define the anatomy of the genitalia, locate the urethral meatus, palpate the scrotum or labia and the inguinal regions for testes (palpable gonads almost always indicate the presence of testicular tissue and thus that the infant is a genetic male), and look for any other anatomic abnormalities. Ultrasonography is helpful in demonstrating the presence or absence of a uterus and can often locate the gonads. A rapid karyotype (such as fluorescent in situ hybridization of interphase nuclei for X and Y

chromosomes) can quickly determine the genetic sex of the infant. These results are all likely to be available before the results of hormonal testing and together allow the clinical team to advise the parents as to the genetic sex of the infant and the anatomy of internal reproductive structures. Injection of contrast medium into the urogenital sinus of female pseudohermaphrodites demonstrates a vagina and uterus and is essential for the surgeon to formulate a plan for surgical management.

Prenatal Diagnosis and Treatment.

Prenatal diagnosis of 21-hydroxylase is possible late in the first trimester by analysis of DNA obtained by chorionic villus sampling or during the second trimester by amniocentesis. This is usually done because the parents already have an affected child. Most often, the *CYP21* gene is analyzed for frequently occurring mutations, but closely linked, highly polymorphic microsatellite markers may be used instead if an affected child (i.e., the proband) is available for genetic comparison.

Besides genetic counseling, the main goal of prenatal diagnosis is to facilitate appropriate prenatal treatment of affected females. Recommendations for pregnancies at risk consist of administration of dexamethasone, a steroid that readily crosses the placenta, in an amount of 20?µg/kg prepregnancy maternal weight daily in two or three divided doses. This suppresses secretion of steroids by the fetal adrenal, including secretion of adrenal androgens. If started by 6 wk of gestation, this ameliorates the virilization of the external genitalia in affected females. Chorionic villus biopsy is then performed to determine the sex and genotype of the fetus; therapy is continued only if the fetus is an affected female. DNA analysis of fetal cells isolated from maternal plasma for sex determination and *CYP21* gene analysis may permit earlier identification of the affected female fetus, but this is not yet widely used. No specific deleterious effects have been observed in children exposed to this therapy, but at present there is insufficient information to determine whether there are any long-term risks, particularly in the males and unaffected females who derive no benefit from the treatment. Maternal side effects of prenatal treatment have included edema, excessive weight gain, hypertension, glucose intolerance, cushingoid facial features, and severe striae.

Newborn Screening.

Because 21-hydroxylase deficiency is often undiagnosed in affected males until they have severe adrenal insufficiency, many American states and other countries have instituted newborn screening programs. These programs analyze 17-hydroxyprogesterone levels in dried blood obtained by heel-stick and absorbed on filter paper cards; the same cards are screened in parallel for other congenital conditions such as hypothyroidism and phenylketonuria. Potentially affected infants are typically recalled for additional testing (e.g., electrolytes and repeat 17-hydroxyprogesterone determination) at approximately 2 wk of age. Infants with salt-wasting disease often have abnormal electrolytes by this age but are usually not severely ill. Thus, screening programs seem to be effective in preventing many cases of adrenal crisis in affected males. The nonclassic form of the disease is not reliably detected by newborn screening, but this is of little clinical significance because adrenal insufficiency does not occur in this type of 21-hydroxylase deficiency.

The main problem with current newborn screening programs is that to reliably detect all affected infants, the cut-off 17-hydroxyprogesterone levels for recalls are set so low that there is a very high frequency of false-positive results (i.e., the test has high sensitivity and low specificity). This problem is worst in premature infants. Genotyping for *CYP21* might improve specificity but is not routinely available.

Treatment

GLUCOCORTICOID REPLACEMENT.

Cortisol deficiency is treated with glucocorticoids. Treatment also suppresses excessive production of androgens by the adrenal cortex and thus minimizes problems such as excessive growth and skeletal maturation and virilization. This often requires larger glucocorticoid doses than are needed in other forms of adrenal insufficiency, typically 10–20?mg/m^2 /24?hr of hydrocortisone daily administered orally in three divided doses. Double or triple doses are indicated during periods of stress, such as infection or surgery.

Glucocorticoid treatment must be continued indefinitely in all patients with classic 21-hydroxylase deficiency but may not be necessary in patients with nonclassic disease unless signs of androgen excess are present. Therapy must be individualized. It is desirable to maintain linear growth along percentile lines; crossing to higher height percentiles may suggest undertreatment, whereas loss of height percentiles often indicates overtreatment with glucocorticoids. Overtreatment is also suggested by excessive weight gain. Pubertal development should be monitored by periodic examination, and skeletal maturation is evaluated by serial radiographs of the hand and wrist for bone age. Hormone levels, particularly 17-hydroxyprogesterone and androstenedione, should be measured early in the morning, before taking the morning medications, or at a consistent time in relation to

medication dosing. In general, desirable 17-hydroxyprogesterone levels are in the high normal range or several times normal; low-normal levels can usually be achieved only with excessive glucocorticoid doses.

Menarche occurs at the appropriate age in most girls in whom good control has been achieved. However, it may be delayed in girls with suboptimal control.

Children with simple virilizing disease, particularly males, are frequently not diagnosed until 3–7 yr of age, at which time skeletal maturation may be 5 yr or more in advance of chronologic age. In some children, especially if the bone age is 12 yr or more, spontaneous gonadotropin-dependent puberty may occur when treatment is instituted, because therapy with hydrocortisone has suppressed production of adrenal androgens and stimulated release of pituitary gonadotropins if the appropriate level of hypothalamic maturation is present. This form of superimposed true precocious puberty may be treated with a gonadotropin hormone–releasing

hormone analogue such as leuprolide.

Males with 21-hydroxylase deficiency who have had inadequate corticosteroid therapy may develop adrenal rest testicular tumors, which usually regress with increased steroid dosage. Testicular MRI, ultrasonography, and color flow Doppler examination help define the character and extent of disease. Testis-sparing surgery for steroid-unresponsive tumors has been reported.

MINERALOCORTICOID REPLACEMENT.

Patients with salt-wasting disease (i.e., aldosterone deficiency) require mineralocorticoid replacement with fludrocortisone. Infants may have very high mineralocorticoid requirements in the first few months of life, usually 0.1–0.3?mg daily in two divided doses but occasionally up to 0.4?mg daily, and often require sodium supplementation (sodium chloride, 1–3?g) in addition to the mineralocorticoid. Older infants and children are usually maintained with 0.05–0.1?mg daily of fludrocortisone. In some patients, simple virilizing disease may be easier to control with a low dose of fludrocortisone in addition to hydrocortisone even when these patients have normal aldosterone levels in the absence of mineralocorticoid replacement. Therapy is evaluated by monitoring of vital signs; tachycardia and hypertension are signs of overtreatment with mineralocorticoids. Serum electrolytes should be measured frequently in early infancy as therapy is adjusted. Plasma renin activity is a useful way to determine adequacy of therapy; it should be maintained in or near the normal range but not suppressed.

Additional approaches to improve outcome include an antiandrogen with an aromatase inhibitor (blocks conversion of androgens to estrogen); growth hormone with or without LHRH agonists; and adrenalectomy for poor controlled patients.

SURGICAL MANAGEMENT OF AMBIGUOUS GENITALIA.

Significantly virilized females usually undergo surgery between 4–12 mo of age. If there is marked clitoromegaly, the clitoris is reduced in size, with partial excision of the corporal bodies and preservation of the neurovascular bundle. Vaginoplasty and correction of the urogenital sinus usually are performed at the time of clitoral surgery; revision in adolescence is often necessary.

Risks and benefits of surgery should be fully discussed with parents of affected females. There is limited long-term follow-up of functional outcomes in patients who have undergone modern surgical procedures. Sex assignment of infants with intersex conditions is usually based on expected sexual functioning and fertility in adulthood with early surgical correction of the external genitals to conform with the sex assignment. However, lay and medical opponents of this practice state that it ignores any prenatally biased gender role predisposition and precludes the patient from having any decision as to his or her own preferred sexual identity and what surgical correction of the genitals should be performed. These individuals and groups say treatment should be aimed primarily at educating patient, family, and others about the medical condition, its treatment, and how to deal with the intersex condition. They propose that surgery should be delayed until the patient decides on what, if any, correction should be performed. Whether this would be a successful practice in our society requires long-term follow-up studies.

570.2 Congenital Adrenal Hyperplasia due to 11ß-Hydroxylase Deficiency

Etiology.

Deficiency of 11ß-hydroxylase is due to a mutation in the *CYP11B1* gene located on chromosome 8q24. *CYP11B1* mediates 11-hydroxylation of 11-deoxycortisol to cortisol. Because 11-deoxycortisol is not converted to cortisol, levels of corticotropin are high. In consequence, precursors—particularly 11-deoxycortisol and deoxycorticosterone—accumulate and are shunted into androgen biosynthesis in the same manner as occurs in 21-hydroxylase deficiency. However, the adjacent *CYP11B2* gene encoding aldosterone synthase is unaffected in this disorder, and so patients are able to synthesize aldosterone normally.

11ß-Hydroxylase deficiency accounts for 5–8% of cases of adrenal hyperplasia; its incidence has been estimated as 1/250,000 to 1/100,000. More than 30 different mutations in *CYP11B1* have been identified. The disorder occurs relatively frequently in Israeli Jews of North African origin (1 in 15,000–17,000 live births); in this ethnic group almost all alleles carry a Arg448 to His (R448H) mutation. This disorder presents in a classic, severe form and rarely in a nonclassic, milder form.

Clinical Manifestations.

Although cortisol is not synthesized efficiently, aldosterone synthetic capacity is normal, and some corticosterone is synthesized from progesterone by the intact aldosterone synthase enzyme. Thus, it is unusual for patients to manifest signs of adrenal insufficiency, such as hypotension, hypoglycemia, hyponatremia, and hyperkalemia. Approximately two thirds of patients become hypertensive, although this can take several years without treatment to develop. Hypertension is probably a consequence of elevated levels of deoxycorticosterone, which has mineralocorticoid activity, or metabolites thereof. Infants may transiently develop signs of mineralocorticoid deficiency after treatment with hydrocortisone is instituted. This is presumably due to sudden suppression of deoxycorticosterone secretion in a patient with atrophy of the zona glomerulosa caused by chronic suppression of renin activity.

All signs and symptoms of androgen excess that are found in 21-hydroxylase deficiency may also occur in 11-hydroxylase deficiency.

Laboratory Findings.

Plasma levels of 11-deoxycortisol and deoxycorticosterone are elevated. Because deoxycorticosterone and metabolites have mineralocorticoid activity, plasma renin activity is suppressed. Consequently, aldosterone levels are low even though the ability to synthesize aldosterone is intact. Hypokalemic alkalosis occasionally occurs.

Treatment.

Patients are treated with hydrocortisone in doses similar to those used for

21-hydroxylase deficiency. Mineralocorticoid replacement is sometimes transiently required in infancy but is rarely necessary otherwise. Hypertension often resolves with glucocorticoid treatment but may require additional therapy if it is of long standing. Calcium channel blockers may be beneficial under these circumstances.

570.3 Congenital Adrenal Hyperplasia due to 3ß-Hydroxysteroid Dehydrogenase Deficiency

Etiology.

Deficiency of 3ß-hydroxysteroid dehydrogenase (3ß-HSD) occurs in fewer than 2% of patients with adrenal hyperplasia. This enzyme is required for conversion of ?5 steroids

---

(pregnenolone, 17-hydroxypregnenolone, dehydroepiandrosterone [DHEA]) to ?4 steroids (progesterone, 17-hydroxyprogesterone, and androstenedione). Thus, deficiency of the enzyme results in decreased synthesis of cortisol, aldosterone, and androstenedione but increased secretion of DHEA (see Fig. 568–1). The 3ß-HSD enzyme expressed in the adrenal cortex and gonad is encoded by the *HSD3B2* gene located on chromosome 1. Over 30 mutations in the *HSD3B2* gene have been described in patients with 3ß-HSD deficiency.

Clinical Manifestations.

Because cortisol and aldosterone are not synthesized in patients with the classic form of the disease, infants are prone to salt-wasting crises. Because androstenedione and testosterone are not synthesized, boys are incompletely virilized. Varying degrees of hypospadias may occur, with or without bifid scrotum or cryptorchidism. Because DHEA levels are elevated and this hormone is a weak androgen, girls are mildly virilized, with slight to moderate clitoral enlargement. Postnatally, continued excessive DHEA secretion can cause precocious adrenarche. During adolescence and adulthood, hirsutism, irregular menses, and polycystic ovarian disease occur in females. Males manifest variable degrees of hypogonadism, although appropriate male secondary sexual development may occur. A persistent defect of testicular 3ß-HSD is demonstrated, however, by the high ?5:?4 steroid ratio in testicular effluent.

Laboratory Findings.

The hallmark of this disorder is the marked elevation of the ?5 steroids (such as 17-hydroxypregnenolone and DHEA) preceding the enzymatic block. Patients may also have elevated levels of 17-hydroxyprogesterone because of the extra-adrenal 3ß-HSD activity that occurs in peripheral tissues; these patients may be mistaken for patients with 21-hydroxylase deficiency. However, the ratio of 17-hydroxypregnenolone:17-hydroxyprogesterone is markedly elevated in 3ß-HSD deficiency, in contrast to the decreased ratio in 21-hydroxylase deficiency. Plasma renin activity is elevated in the salt-wasting form.

It is not unusual for children with premature adrenarche, or women with signs of androgen excess, to have mild to moderate elevations in DHEA levels. It has been suggested that such individuals have “nonclassic 3ß-HSD deficiency.” However, mutations in the *HSD3B2* gene are not found in most such individuals and the nonclassic form of this deficiency must be quite rare.

Treatment.

Patients require glucocorticoid and mineralocorticoid replacement with hydrocortisone and fludrocortisone, respectively, as in 21-hydroxylase deficiency. Incompletely virilized genetic males in whom a male sex of rearing is contemplated may benefit from several injections of a depot form of testosterone early in infancy to increase the size of the phallus. They may also require testosterone replacement at puberty.

570.4 Congenital Adrenal Hyperplasia due to 17-Hydroxylase Deficiency

Etiology.

Fewer than 1% of CAH cases are caused by 17-hydroxylase deficiency. A single polypeptide, CYP17, catalyzes two distinct reactions: 17-hydroxylation of pregnenolone and progesterone to 17-hydroxypregnenolone and 17-hydroxyprogesterone, respectively, and the 17,20-lyase reaction mediating conversion of 17-hydroxypregnenolone to DHEA and, to a lesser extent, 17-hydroxyprogesterone to ?4-androstenedione. DHEA and androstenedione are steroid precursors of testosterone and estrogen (see Fig. 568–1). The enzyme is expressed in both the adrenal cortex and the gonads and is encoded by a gene on chromosome 10. Most mutations affect both the hydroxylase and lyase activities, but rare mutations can affect either activity alone.

Clinical Manifestations and Laboratory Findings.

Patients with 17-hydroxylase deficiency cannot synthesize cortisol, but their ability to synthesize corticosterone is intact. Because corticosterone is an active glucocorticoid, patients do not develop adrenal insufficiency. However, deoxycorticosterone, the immediate precursor of corticosterone, is synthesized in excess. This can cause hypertension, hypokalemia, and suppression of renin and aldosterone secretion, as occurs in 11-hydroxylase deficiency. However, in contrast to 11-hydroxylase deficiency, patients with 17-hydroxylase deficiency are unable to synthesize sex hormones. Affected males are incompletely virilized and present as phenotypic females (but gonads are usually palpable in the inguinal region or the labia) or with sexual ambiguity (male pseudohermaphroditism). Affected females usually present with failure of sexual development at the expected time of puberty. 17-Hydroxylase deficiency in females must be considered in the differential diagnosis of primary hypogonadism (see Chapter 580). In addition to the increased DOC, suppressed renin and aldosterone, and decreased 17-hydroxylated steroids, cortisol and sex steroids are unresponsive to stimulation with ACTH and human chorionic

gonadotropin, respectively.

Treatment.

Patients with 17-hydroxylase deficiency require cortisol replacement to suppress secretion of deoxycorticosterone and thus control hypertension. Additional antihypertensive medication may be required. Females require estrogen replacement at puberty. Genetic males may require either estrogen or androgen supplementation depending on the sex of rearing. As with androgen insensitivity syndrome (see Chapter 582), genetic males with severe 17-hydroxylase deficiency being reared as females require gonadectomy at or before adolescence because of the chance of malignant transformation of abdominal testes.

570.5 Lipoid Adrenal Hyperplasia

Etiology.

Lipoid adrenal hyperplasia is a rare disorder, reported in fewer than 100 patients, the majority of whom are Japanese. In this disorder there is marked accumulation of cholesterol and lipids in the adrenal cortex and gonads, associated with severe impairment of all steroidogenesis. Lipoid adrenal hyperplasia is usually caused by mutations in the gene for steroidogenic acute regulatory protein (StAR), a mitochondrial protein that promotes the movement of cholesterol from the outer to the inner mitochondrial membrane. Mutations in the P450scc gene have been reported in two patients with lipoid adrenal hyperplasia.

Some cholesterol is able to enter mitochondria even in the absence of StAR, so it might be supposed that this disorder would not completely impair steroid biosynthesis. However, the accumulation of cholesterol in the cytoplasm is cytotoxic, eventually leading to death of all steroidogenic cells in which StAR is normally expressed. This occurs prenatally in the adrenals and testes. However, the ovaries do not normally synthesize steroids until puberty, so cholesterol does not accumulate and the ovaries can retain the capacity to synthesize estrogens until adolescence.

Although estrogens synthesized by the placenta are required to maintain pregnancy, the placenta does not require StAR for steroid biosynthesis. Thus, mutations of StAR are not prenatally lethal.

Clinical Manifestations.

Patients with lipoid adrenal hyperplasia are usually unable to synthesize any adrenal steroids. Thus, affected infants are likely to be confused with those with adrenal hypoplasia. Salt-losing manifestations are usual, and many infants die in early infancy. Genetic males are unable to synthesize androgens and thus are phenotypically female but with gonads. Genetic females appear normal at birth and may undergo feminization at puberty with menstrual bleeding. They

---

too, however, progress to hypergonadotropic hypogonadism when accumulated cholesterol kills granulosa (i.e., steroid synthesizing) cells in the ovary.

Laboratory Findings.

Adrenal and gonadal steroid hormone levels are low in lipoid adrenal hyperplasia, with a decreased or absent response to stimulation (ACTH, human chorionic gonadotropin). Plasma renin levels are increased.

Imaging studies of the adrenal gland demonstrating massive adrenal enlargement in the newborn help establish the diagnosis of lipoid adrenal hyperplasia.

Treatment.

Patients require glucocorticoid and mineralocorticoid replacement. Genetic males are usually assigned a female sex of rearing; thus both genetic males and females require estrogen replacement at the expected age of puberty.

570.6 Aldosterone Synthase Deficiency

Etiology.

This is a rare autosomal recessive disorder in which conversion of corticosterone to aldosterone is impaired; a group of Iranian Jewish patients has been most thoroughly studied. Most cases result from mutations in the *CYP11B2* gene coding for aldosterone synthase; however, linkage to *CYP11B2* has been excluded in other kindreds. Aldosterone synthase mediates the three final steps in the synthesis of aldosterone from deoxycorticosterone (11-hydroxylation, 18-hydroxylation, 18-oxidation). Although 11-hydroxylation is required to convert deoxycorticosterone to corticosterone, this conversion can also be catalyzed by the related enzyme, CYP11B1, located in the fasciculata, which is unaffected in this disorder. For the same reason, these patients have normal cortisol biosynthesis.

The disease has previously been divided into two types termed *corticosterone methyloxidase deficiency types I and II.* They differ only in levels of the immediate precursor of aldosterone, 18-hydroxycorticosterone; levels are low in type I deficiency and elevated in type II deficiency. These differences do not correspond in a simple way to particular mutations and are of limited clinical importance.

Clinical Manifestations.

Infants with aldosterone synthase deficiency may have severe electrolyte abnormalities with hyponatremia, hyperkalemia, and acidosis. However, because cortisol synthesis is unaffected, infants rarely become as ill as untreated infants with salt-losing forms of congenital adrenal hyperplasia such as 21-hydroxylase deficiency. Thus, some infants escape diagnosis. They may present later in infancy

or in early childhood with failure to thrive and poor growth. Adults often are asymptomatic, although they may develop electrolyte abnormalities when depleted of sodium through procedures such as bowel preparation for a barium enema.

Laboratory Findings.

Infants have elevated plasma renin activity. Aldosterone levels are decreased; they may be at the lower end of the normal range but are always inappropriately low for the degree of hyperkalemia or hyperreninemia. Corticosterone levels are often elevated. As mentioned, some but not all patients have marked elevation of 18-hydroxycorticosterone but low levels of this steroid do not exclude the diagnosis. In kindreds in which 18-hydroxycorticosterone levels are elevated in affected individuals, this biochemical abnormality persists in adults even when they have no electrolyte abnormalities.

Treatment.

Treatment consists of giving enough fludrocortisone (0.05–0.3?mg daily), sodium chloride, or both to return plasma renin levels to normal. With increasing age, salt-losing signs usually improve and drug therapy can often be discontinued.

570.7 Glucocorticoid-Suppressible Hyperaldosteronism

Etiology.

Glucocorticoid-suppressible aldosteronism (glucocorticoid-remediable aldosteronism, familial hyperaldosteronism type I) is an autosomal dominant form of low-renin hypertension in which hyperaldosteronism is rapidly suppressed by glucocorticoid administration. This unusual effect of glucocorticoids suggests that in this disorder is regulated by ACTH aldosterone secretion instead of by the renin-angiotensin system. In addition to abnormally regulated secretion of aldosterone, there is marked overproduction of 18-hydroxycortisol and 18-oxocortisol. The synthesis of these steroids requires both 17-hydroxylase *(CYP17)* activity, which is expressed only in the zona fasciculata, and aldosterone synthase *(CYP11B2)* activity, which is normally expressed only in the zona glomerulosa. Together, these features imply that aldosterone synthase is being expressed in a manner similar to the closely related enzyme steroid 11-hydroxylase *(CYP11B1).* The disorder is caused by unequal meiotic crossing over events between the *CYP11B1* and *CYP11B2* genes, which are closely linked on chromosome 8q24. An additional “hybrid” gene is produced, having regulatory sequences of *CYP11B1* juxtaposed with coding sequences of *CYP11B2.* This results in the inappropriate expression of a *CYP11B2*-like enzyme with aldosterone synthase activity in the adrenal fasciculata.

Clinical Manifestations.

Some affected children have no symptoms, the diagnosis being established after incidental discovery of moderate hypertension, typically about 30?mm Hg higher than unaffected family members of the same age. Others have more symptomatic hypertension with headache, dizziness, and visual disturbances. A strong family history of early-onset hypertension or early strokes may alert the clinician to the diagnosis. Some patients have chronic hypokalemia, but this is not a consistent finding and is usually mild.

Administration of dexamethasone, 25?µg/kg/day in divided doses, suppresses aldosterone secretion. Hypertension resolves in patients in whom the hypertension is not severe or of long standing.

Laboratory Findings.

Patients have elevated plasma and urine levels of aldosterone and suppressed plasma renin activity. As mentioned, hypokalemia is not consistently present. Urinary and plasma levels of 18-oxocortisol and 18-hydroxycortisol are markedly increased. The hybrid *CYP11B1/CYP11B2* gene can be readily detected by molecular genetic methods. However, these assays are not routinely available.

Treatment.

Glucocorticoid-suppressible hyperaldosteronism is managed by daily administration of a glucocorticoid, usually prednisone or dexamethasone. If necessary, effects of aldosterone can be blocked with a potassium-sparing diuretic such as spironolactone, eplerenone, or amiloride. If hypertension is of long standing, additional antihypertensive medication may be required, such as a calcium channel blocker.

Because of the autosomal dominant mode of inheritance, at-risk family members should be investigated for this easily treated cause of hypertension.

Chapter 571 - Cushing Syndrome

Cushing syndrome is the result of abnormally high blood levels of cortisol or other glucocorticoids. This can be iatrogenic or the result of endogenous cortisol secretion, either due to an adrenal tumor or to hypersecretion of corticotropin (adrenocorticotropic hormone [ACTH]) by the pituitary (Cushing disease) or by a tumor (Box 571–1).

Etiology.

By far the most common cause of Cushing syndrome is prolonged exogenous administration of glucocorticoid hormones, especially in the high doses used to treat lymphoproliferative disorders. This rarely represents a diagnostic challenge, but management of hyperglycemia, hypertension, weight gain, linear growth retardation, and osteoporosis often complicates therapy with corticosteroids.

Endogenous Cushing syndrome is most often caused in infants by a *functioning adrenocortical tumor*, usually a malignant carcinoma but occasionally a benign adenoma (see Chapter 573).

Box 571-1. Etiologic Classification of Adrenocortical Hyperfunction

- Excess androgen
  - Congenital adrenal hyperplasia
    - 21-Hydroxylase (P450c21) deficiency
    - 11 ß-Hydroxylase (p450c11) deficiency
    - 3ß-Hydroxysteroid dehydrogenase defect
  - Tumor
    - Carcinoma
    - Adenoma
- Excess cortisol (Cushing syndrome)
  - Bilateral adrenal hyperplasia
    - Hypersecretion of corticotropin (Cushing disease)
    - Ectopic secretion of corticotropin
    - Exogenous corticotropin
  - Adrenocortical nodular dysplasia
  - Pigmented nodular adrenocortical disease (Carney complex)
  - Tumor
    - Carcinoma
    - Adenoma
- Excess mineralocorticoid (hypertensive hypokalemic syndrome)
  - Primary hyperaldosteronism
    - Aldosterone-secreting adenoma

syndrome)

- Primary hyperaldosteronism
  - Aldosterone-secreting adenoma
  - Bilateral micronodular adrenocortical hyperplasia
  - Glucocorticoid-suppressible aldosteronism
  - Tumor
    - Adenoma
    - Carcinoma
- Desoxycorticosterone excess
  - Congenital adrenal hyperplasia
    - 11ß-Hydroxylase (P450c11)
    - 17a-Hydroxylase (P450c17)
  - Tumor (carcinoma)
- Apparent mineralocorticoid excess
  - 11ß-Hydroxysteroid dehydrogenase deficiency

Excess estrogen (adrenal feminization syndrome)

- Carcinoma
- Adenoma

Mixed hypercorticism-tumor

Patients with these tumors often exhibit signs of hypercortisolism mixed with signs of hypersecretion of other steroids such as androgens, estrogens, and aldosterone.

Although extremely rare in infants, the most common etiology of endogenous Cushing syndrome in children older than 7 yr of age is Cushing disease, in which excessive ACTH secreted by a pituitary adenoma causes bilateral adrenal hyperplasia. Such adenomas are often too small to detect by imaging techniques and are termed *microadenomas.* They consist principally of chromophobe cells and frequently have positive immunostaining for ACTH and its precursor, pro-opiomelanocortin (POMC).

ACTH-dependent Cushing syndrome may also result from *ectopic production of ACTH,* although this is uncommon in children. Ectopic ACTH secretion in children has been associated with islet cell carcinoma of the pancreas, neuroblastoma or ganglioneuroblastoma, hemangiopericytoma, Wilms tumor, and thymic carcinoid.

Primary pigmented nodular adrenocortical disease (PPNAD) is a distinctive form of ACTH-independent Cushing syndrome, usually presenting before 20 yr of age. It may occur as an isolated event or, more commonly, as a familial disorder with other manifestations. The adrenal glands are small and have characteristic multiple, small (<4?mm in diameter), pigmented (black) nodules containing large cells with cytoplasm and lipofuscin; between the nodules, there is cortical atrophy. This adrenal disorder occurs as a component of **Carney complex**, an autosomal dominant disorder also consisting of centrofacial lentigines and blue nevi, cardiac and cutaneous myxomas, pituitary, thyroid, and testicular tumors, and pigmented melanotic schwannomas. Carney complex is inherited in an autosomal dominant manner, although sporadic cases occur. Genetic loci for Carney complex have been mapped to chromosome 2p16 and to the gene for the type 1a regulatory subunit of protein kinase A on chromosome 17q22-24.

ACTH-independent Cushing syndrome with nodular hyperplasia and adenoma formation occurs rarely in cases of *McCune-Albright syndrome,* with symptoms beginning in infancy or childhood. McCune-Albright syndrome is caused by a somatic mutation of a G protein, G_{sa} , resulting in inhibition of guanosine triphosphatase activity and constitutive activation of adenylate cyclase. When the mutation is present in adrenal tissue, cortisol and cell division are stimulated independently of ACTH. Other tissues in which activating mutations may occur are bone (producing fibrous dysplasia), gonads, thyroid, and pituitary. Clinical manifestations depend on which tissues are affected.

Adrenocortical lesions including diffuse hyperplasia, nodular hyperplasia, adenoma, or, rarely, carcinoma, may occur as part of the multiple endocrine neoplasia type 1 syndrome, an autosomal dominant disorder, in which there is homozygous inactivation of a putative tumor suppressor gene on chromosome 11q13.

Clinical Manifestations.

Symptoms have been recognized in infants younger than 1 yr of age. The disorder appears to be more severe and the clinical findings more flagrant in infants than when the onset occurs in older children. The face is rounded, with prominent cheeks and a flushed appearance (moon facies). Generalized obesity is common in younger children. In children with adrenal tumors, signs of abnormal masculinization occur frequently; accordingly, there may be hypertrichosis on the face and trunk, pubic hair, acne, deepening of the voice, and enlargement of the clitoris in girls. Growth is impaired, with length falling below the 3rd percentile, except when significant virilization produces normal or even accelerated growth. Hypertension is common and may occasionally lead to heart failure. An increased susceptibility to infection

may also lead to fatal sepsis.

In older children, in addition to obesity, short stature is a common presenting feature. Gradual onset of obesity and deceleration or cessation of growth may be the only early manifestations. Older children most often have more severe obesity of the face and trunk compared with the extremities. Purplish striae on the hips, abdomen, and thighs are common. Pubertal development may be delayed, or amenorrhea may occur in girls past menarche. Weakness, headache, and emotional lability may be prominent. Hypertension and hyperglycemia usually occur; hyperglycemia may progress to frank diabetes. Osteoporosis is common and may cause pathologic fractures.

Laboratory Findings.

Cortisol levels in blood are normally elevated at 8 am and decrease to less than 50% by midnight except in infants and young children in whom a diurnal rhythm is not always established. In patients with Cushing syndrome this circadian rhythm is lost, and cortisol levels at midnight and 8 am are usually comparable. Obtaining diurnal blood samples presents logistical difficulties as part of an outpatient evaluation, but cortisol can be measured in saliva samples, which can be obtained at home at the appropriate times of day. Nighttime salivary cortisol levels are elevated and may be a screening test in obese children.

Urinary excretion of free cortisol is increased. This is best measured in a 24-hr urine sample and is expressed as a ratio of micrograms of cortisol excreted per gram of creatinine. This ratio is independent of body size and completeness of the urine collection.

A single-dose dexamethasone suppression test is often helpful; a dose of 25–30?µg/kg (maximum of 2?mg) given at 11 pm results in a plasma cortisol level of less than 5?µg/dL at 8 am the next morning in normal individuals but not in patients with Cushing syndrome.

A glucose tolerance test is often abnormal despite elevated levels of insulin. Levels of serum electrolytes are usually normal, but potassium may be decreased, especially in tumors with ectopic ACTH secretion.

After the diagnosis of Cushing syndrome has been established, it is necessary to determine whether it is caused by a pituitary adenoma, an ectopic ACTH-secreting tumor, or a cortisol-secreting tumor. ACTH concentrations are usually suppressed in patients with cortisol-secreting tumors, are very high in patients with ectopic ACTH-secreting tumors, but may be normal in patients with ACTH-secreting pituitary adenomas. After an intravenous bolus of corticotropin-releasing hormone (CRH), patients with ACTH-dependent Cushing syndrome have an exaggerated ACTH and cortisol response but those with adrenal tumors show no increase in ACTH and cortisol. The two-step dexamethasone suppression test consists of administration of dexamethasone, 30 and 120?µg/kg/24?hr in four divided doses, on consecutive days. In children with pituitary Cushing syndrome, the larger dose, but not the smaller dose, suppresses serum levels of cortisol. Typically, patients with ACTH-independent Cushing syndrome do not show suppressed cortisol levels with dexamethasone.

CT detects virtually all adrenal tumors larger than 1.5?cm in diameter. MRI may detect ACTH-secreting pituitary adenomas, but many are too small to be seen; the addition of gadolinium contrast increases the sensitivity of detection. Bilateral inferior petrosal blood sampling to measure concentrations of ACTH before and after CRH administration may be required to localize the tumor when a pituitary adenoma is not visualized.

Differential Diagnosis.

Cushing syndrome is frequently suspected in children with obesity, particularly when striae and hypertension are present. Children with simple obesity are usually tall, whereas those with Cushing syndrome are short or have a decelerating growth rate. Although urinary excretion of cortisol is often elevated in simple obesity, salivary nighttime levels of cortisol are normal and cortisol secretion is suppressed by oral administration of low doses of dexamethasone.

Elevated levels of cortisol and ACTH without clinical evidence of Cushing syndrome occur in patients with generalized glucocorticoid resistance. Affected patients may be asymptomatic or exhibit hypertension, hypokalemia, and precocious pseudopuberty; these manifestations are caused by increased mineralocorticoid and adrenal androgens in response to elevated ACTH levels. Mutations in the glucocorticoid receptor have been identified. Absence of cushingoid phenotype in a patient with a pituitary adenoma and biochemically proven Cushing disease has been reported. In this patient, defective cortisone to cortisol conversion resulted in increased cortisol clearance, protecting the patient from cortisol excess.

Treatment.

Transsphenoidal pituitary microsurgery is the treatment of choice in pituitary Cushing disease in children. The overall success rate with follow-up of less than 10 yr is 60–80%. Low postoperative serum or urinary cortisol concentrations appear to be predictive of long-term remission in the majority of cases. Reoperation or pituitary irradiation is performed when relapse occurs.

Cyproheptadine, a centrally acting serotonin antagonist that blocks ACTH release, has been used to treat Cushing disease in adults; remissions are usually not sustained after discontinuation of therapy. This agent is rarely used in children. Inhibitors of adrenal steroidogenesis (metyrapone, ketoconazole, aminoglutethimide) have been used preoperatively to normalize circulating cortisol levels and reduce perioperative morbidity and mortality.

If a pituitary adenoma does not respond to treatment or if ACTH is secreted by an ectopic metastatic tumor, the adrenal glands may need to be removed. This can often be accomplished laparoscopically. Adrenalectomy may lead to increased ACTH secretion by an unresected pituitary adenoma, evidenced mainly by marked hyperpigmentation; this is termed *Nelson syndrome.*

If the lesion is a benign cortical adenoma, unilateral adrenalectomy is indicated.

Such adenomas are occasionally bilateral;

then the treatment of choice is subtotal adrenalectomy. In either instance, an excellent therapeutic result is achieved by removing the tumor. Adrenocortical carcinomas frequently metastasize, especially to the liver and lungs, and the prognosis may be unfavorable despite removal of the primary lesion. Rarely, the tumors are bilateral and require total adrenalectomy. It is often impossible to differentiate benign from malignant tumors by histologic appearance alone.

Management of patients undergoing adrenalectomy requires adequate preoperative and postoperative replacement therapy with a corticosteroid. Tumors that produce corticosteroids usually lead to atrophy of the normal adrenal tissue, and replacement with cortisol is required until there is recovery of the hypothalamic-pituitary-adrenal axis. Postoperative complications have included sepsis, pancreatitis, thrombosis, poor wound healing, and sudden collapse, particularly in infants with Cushing syndrome. Substantial catch-up growth, pubertal progress, and increased bone density occur, but bone density remains abnormal and adult height is often compromised.

Chapter 572 - Primary Aldosteronism

Primary aldosteronism encompasses disorders caused by excessive aldosterone secretion independent of the renin-angiotensin system. These disorders are characterized by hypertension, hypokalemia, and suppression of the renin-angiotensin system.

Aldosterone-secreting adenomas are unilateral and have been reported in children as young as 3.5 yr of age; they mainly affect girls. *Bilateral micronodular adrenocortical hyperplasia* tends to occur in older children and is more frequent in males. Primary aldosteronism due to *unilateral adrenal hyperplasia* may also occur. All are very rare in children. Glucocorticoid-suppressible hyperaldosteronism is discussed in Chapter 570 .

Clinical Manifestations.

Some affected children have no symptoms, the diagnosis being established after incidental discovery of moderate hypertension. Others have severe hypertension (up to 240/150?mm Hg), with headache, dizziness, and visual disturbances. Chronic hypokalemia, if present, may lead to polyuria, nocturia, enuresis, and polydipsia. Muscle weakness and discomfort, tetany, intermittent paralysis, fatigue, and growth failure affect children with severe hypokalemia.

Laboratory Findings.

Hypokalemia occurs frequently. Serum pH and the carbon dioxide and sodium concentrations may be elevated and the serum chloride and magnesium levels decreased. Serum levels of calcium are normal, even in children who manifest tetany. The urine is neutral or alkaline, and kaliuresis is present. Plasma levels of aldosterone may be normal or elevated. Aldosterone concentrations in 24?hr urine collections are always increased. Plasma levels of renin are persistently low, and the ratio of plasma aldosterone concentration to renin activity is always high. Aldosterone does not decrease with sodium chloride administration, and renin does not respond to salt and fluid restriction. Urinary and plasma levels of 18-oxocortisol and 18-hydroxycortisol may be increased but not to the extent seen in glucocorticoid-suppressible hyperaldosteronism.

Treatment.

The treatment of an aldosterone-producing adenoma is surgical removal. This has been performed primarily by laparotomy and adrenalectomy. However, successful enucleation of aldosterone-producing adenomas as well as laparoscopic adrenalectomy are reported. Pharmacologic treatment of hyperaldosteronism due to bilateral adrenal hyperplasia with spironolactone often results in normalization of blood pressure and serum potassium levels.

If the side effects of spironolactone are unacceptable, amiloride may be used and other antihypertensive agents added as necessary. In patients whose condition cannot be controlled medically, unilateral adrenalectomy may be considered.

Chapter 573 - Adrenal Tumors

Adrenocortical tumors are rare in childhood. They occur in all age groups but most commonly in children younger than 10 yr of age. In 2–10% of cases, the tumors are bilateral. Symptoms of endocrine hyperfunction are present in more than 90% of children with adrenal tumors (see Table 571–1). Tumors may be associated with hemihypertrophy, usually occurring during the first few years of life. They are also associated with the Beckwith-Wiedemann syndrome and other congenital defects, particularly genitourinary tract and central nervous system abnormalities and hamartomatous defects.

Germ line mutations in p53 (on chromosome 17p13.1) have been found in patients with isolated adrenal carcinoma as well as in patients with familial clustering of unusual malignancies. Loss of heterozygosity involving chromosomes 2, 4, 11, and 18 and *IGF2* gene overexpression (chromosome 11p15.5) have also been reported in sporadic adrenocortical carcinomas.

573.1 Virilizing Adrenocortical Tumors

Virilization is the most common presenting symptom. In males, this produces a clinical picture similar to that of simple virilizing congenital adrenal hyperplasia: accelerated growth velocity and muscle development, acne, penile enlargement, and the precocious development of pubic and axillary hair. In females, virilizing tumors of the adrenal gland cause masculinization of a previously normal female with clitoral enlargement, growth acceleration, acne, deepening of the voice, and premature pubic and axillary hair development.

In addition to virilization, 20–40% of children with adrenal cortical tumors also have Cushing syndrome (see Chapter 571). Although virilization may occur alone (50–80%), it is unusual to have Cushing syndrome alone in children with adrenal tumors.

Serum levels of dehydroepiandrosterone (DHEA), DHEA sulfate, and androstenedione are usually elevated, often markedly. Serum levels of testosterone are often increased, usually as a result of peripheral conversion of androstenedione, but infants with predominantly testosterone-secreting adenomas have been reported. Urinary 17-ketosteroids (sex steroid metabolites) are also increased. Many adrenocortical tumors have a relative deficiency of 11ß-hydroxylase activity and secrete increased amounts of deoxycorticosterone; these patients are hypertensive, and their tumors are often malignant.

Tumors can usually be detected by ultrasonography, CT, or MRI. Preoperatively the presence of metastatic disease should be determined by MRI or CT of the chest, abdomen, and pelvis. Differentiation between benign and malignant tumors by histologic criteria often is not possible.

The treatment is surgical. A transperitoneal approach has usually been recommended, but laparoscopic removal is possible. Some of these neoplasms are highly malignant and metastasize widely, but cure with regression of the masculinizing features may follow removal of less malignant encapsulated tumors. Incomplete resection, tumors weighing more than 100?g, tumors larger than 200?cm^3 , age greater than 3.5 yr at diagnosis, symptoms for more than 6 mo, and a marked increase in urinary 17-ketosteroids and 17-hydroxysteroids have been associated with poor prognosis. Postoperatively, patients should be closely monitored biochemically, with frequent determinations of adrenal androgen levels and imaging studies. Recurrent symptoms or biochemical abnormalities should prompt a careful search for metastatic disease. Metastases primarily involve liver, lung, and regional lymph nodes. The majority of metastatic recurrences appear within 1 yr of tumor resection. Repeat surgical resection of metastatic lesions should be performed if possible and adjuvant therapy instituted. Radiation therapy has not been generally helpful. Antineoplastic agents, such as cisplatin and etoposide, ifosfamide and carboplatin, and 5-fluorouracil and leucovorin have had limited use in children, and their success is not established. Therapy with o,p'-DDD (mitotane), an adrenolytic agent, may relieve the symptoms of hypercortisolism or virilization in recurrent disease but does not appear to improve survival. Other agents that interfere with adrenal steroid synthesis, such as ketoconazole, aminoglutethimide, and metyrapone, may also relieve symptoms of steroid excess but do not improve survival.

A neoplasm of one adrenal gland may produce atrophy of the other, because excessive production of cortisol by the tumor suppresses adrenocorticotropic hormone stimulation of the normal gland. Consequently, adrenal insufficiency may follow surgical removal of the tumor. This situation can be avoided by giving 10–25?mg of hydrocortisone every 6?hr, starting on the day of operation and continuing for 3–4 days postoperatively. Adequate quantities of water, sodium chloride, and glucose must also be provided.

573.2 Feminizing Adrenal Tumors

Feminizing adrenocortical tumors may be either carcinomas or benign adenomas. They may produce only estrogens or, in addition, androgens, cortisol, or mineralocorticoids (see Fig. 568–1). High levels of aromatase activity and expression of the *CYP19 (P450arom)* gene, absent in normal adrenal tissue, are found in these tumors.

Such tumors may become symptomatic at any age after 6 mo. Gynecomastia in males or premature thelarche in girls is often the initial manifestation. Growth and development may be otherwise normal, or concomitant virilization may occur, evidenced by acne, deep voice, penile or clitoral enlargement, and advanced

osseous maturation. Hypertension is common in affected adults but has not been observed in children.

In addition to elevated plasma and urinary levels of estrogens, there are often elevated levels of adrenal androgens (i.e., dehydroepiandrosterone and its sulfate) in plasma and 17-ketosteroids in urine. Plasma gonadotropin levels are suppressed, and gonadotropin-releasing hormone stimulation does not elicit a response. Tumors may appear calcified on radiographs but are usually localized by CT.

If the tumor can be resected, gynecomastia regresses and hormone values return to normal.

Chapter 574 - Pheochromocytoma

Pheochromocytoma, a catecholamine-secreting tumor, arises from chromaffin cells. The most common site of origin (approximately 90%) is the adrenal medulla; however, tumors may develop anywhere along the abdominal sympathetic chain and are likely to be located near the aorta at the level of the inferior mesenteric artery or at its bifurcation. They also appear in the periadrenal area, the urinary bladder or ureteral walls, the thoracic cavity, and the cervical region. Ten per cent occur in children, in whom they present most frequently between 6 and 14 yr of age. Tumors vary from 1–10?cm in diameter; they are found more often on the right side than on the left. In more than 20% of affected children, the adrenal tumors are bilateral; and in 30–40% of children, tumors are found in both the adrenal and extra-adrenal areas or only in an extra-adrenal area.

Pheochromocytoma may be inherited as an autosomal dominant trait. In affected families, the ages of patients at the time of diagnosis have varied from the 1st to 5th decades of life; more than half the patients have had multiple tumors.

Pheochromocytomas may also be associated with other syndromes such as neurofibromatosis and von Hippel-Lindau disease and as a component of multiple endocrine neoplasia (MEN) syndromes MEN-2A and MEN-2B. The *NF1* neurofibromatosis gene is a tumor suppressor gene mapping to chromosome 17q11.2. Germ line mutations of the *RET* proto-oncogene on chromosome 10 (10q11.2) have been found in families with MEN-2A and MEN-2B, and germ line mutations in a tumor suppressor gene on chromosome 3p25-26 have been identified in von Hippel-Lindau syndrome. Pheochromocytoma is also associated with tuberous sclerosis, Sturge-Weber syndrome, and ataxia-telangiectasia. Somatic mutations of genes associated with familial cancer syndromes have been found in nonfamilial forms of pheochromocytoma.

Clinical Manifestations.

The clinical features of pheochromocytoma result from excessive secretion of epinephrine and norepinephrine. All patients have hypertension at some time. Paroxysmal hypertension should particularly suggest pheochromocytoma as a diagnostic possibility. However, the hypertension in children is more often sustained rather than paroxysmal, in contrast to adults. When there are paroxysms of hypertension, the attacks are usually infrequent at first but become more frequent and eventually give way to a continuous hypertensive state. Between attacks of hypertension, the patient may be free of symptoms. During attacks, the patient complains of headache, palpitations, abdominal pain, and dizziness; pallor, vomiting, and sweating also occur. Convulsions and other manifestations of hypertensive

encephalopathy may occur. In severe

cases, precordial pains radiate into the arms and pulmonary edema and cardiac and hepatic enlargement may develop. The child has a good appetite but because of hypermetabolism does not gain weight, and severe cachexia may develop. Polyuria and polydipsia can be sufficiently severe to suggest diabetes insipidus. Growth failure may be striking. The blood pressure may range from 180–260?mm Hg systolic and 120–210?mm Hg diastolic, and the heart may be enlarged. Ophthalmoscopic examination may reveal papilledema, hemorrhages, exudate, and arterial constriction.

Laboratory Findings.

The urine may contain protein, a few casts, and occasionally glucose. Gross hematuria suggests that the tumor is in the bladder wall. Polycythemia is occasionally observed. The diagnosis is established by demonstration of elevated blood or urinary levels of catecholamines and their metabolites.

Pheochromocytomas produce norepinephrine and epinephrine. Normally, norepinephrine in plasma is derived from both the adrenal gland and adrenergic nerve endings whereas epinephrine is derived primarily from the adrenal gland. In contrast to adults with pheochromocytoma in whom both norepinephrine and epinephrine are elevated, children with pheochromocytoma predominantly excrete norepinephrine. Total urinary catecholamine excretion usually exceeds 300?µg/24?hr. Urinary excretion of vanillylmandelic acid (VMA, 3-methoxy-4-hydroxymandelic acid), the major metabolite of epinephrine and norepinephrine, is increased, as is excretion of metanephrine (see Fig. 568–2). Catecholamine levels can be measured by radioimmunoassay and high-performance liquid chromatography methods. Excretion of catecholamine metabolites may be similar in children with neuroblastoma and pheochromocytoma, but neuroblastoma does not usually produce hypertension. Urinary levels of most catecholamines are higher in those with pheochromocytoma, although levels of dopamine and homovanillic acid are usually higher in neuroblastoma. Daily urinary excretion of these compounds by unaffected children increases with age; and vanilla-containing foods and fruits can produce falsely elevated levels of VMA. Certain drugs interfere with fluorometric determinations of catecholamines.

Most tumors in the area of the adrenal gland are readily localized by ultrasonography or by CT or MRI; their frequent bilateral occurrence must not be forgotten. Extra-adrenal tumors may be difficult to detect. ^{131}I-Metaiodobenzylguanidine (MBIG) is taken up by chromaffin tissue anywhere in the body and is useful for localizing small tumors. Venous catheterization with sampling of blood at different levels for catecholamine determinations is now only rarely necessary for localizing the tumor.

Differential Diagnosis.

Various causes of hypertension in children must be considered, such as renal or renovascular disease, coarctation of the aorta, hyperthyroidism, Cushing syndrome, deficiencies of 11ß-hydroxylase, 17ß-hydroxylase, or 11ß-hydroxysteroid dehydrogenase, primary aldosteronism, adrenal cortical tumors, and essential hypertension (see Chapter 437). A nonfunctioning kidney may result from compression of a ureter or of a renal artery by a pheochromocytoma. Paroxysmal hypertension may be associated with porphyria or familial dysautonomia. Urinary excretion of VMA is low in familial dysautonomia because of a defect in release rather than in synthesis of catecholamines. Cerebral disorders, diabetes insipidus, diabetes mellitus, and hyperthyroidism must also be considered in the differential diagnosis. Hypertension in patients with neurofibromatosis may be caused by renal vascular involvement and by concurrent pheochromocytoma.

Neuroblastoma, ganglioneuroblastoma, and ganglioneuroma frequently produce catecholamines. Secreting neurogenic tumors commonly produce hypertension, excessive sweating, flushing, pallor, rash, polyuria, and polydipsia. Chronic diarrhea may be associated with these tumors, particularly with ganglioneuroma, and at times may be sufficiently persistent to suggest the celiac syndrome.

Treatment.

Removal of these tumors results in cure, but the operation is very high risk. Careful preoperative, intraoperative, and postoperative management is essential. Preoperative a- and ß-adrenergic blockade and fluid administration are required. Because these tumors are often multiple in children, a thorough transabdominal exploration of all the usual sites offers the best chance of finding all of them. Appropriate choice of anesthesia and expansion of blood volume with appropriate fluids during surgery are critical to avoid a precipitous drop in blood pressure during operation or within 48?hr postoperatively. Manipulation and excision of these tumors result in marked increases in catecholamine secretion that cause rises in blood pressure and heart rate. Surveillance must continue postoperatively.

Although these tumors often appear malignant histologically, the only accurate indicators of malignancy are the presence of metastatic disease, local invasiveness that precludes complete resection, or both. Approximately 10% of all adrenal pheochromocytomas are malignant. Such tumors are very rare in childhood; pediatric malignant pheochromocytomas occur more frequently in extra-adrenal sites. Prolonged follow-up is indicated because functioning tumors at other sites may be manifested many years after the initial operation. Examination of relatives of affected patients may reveal other persons harboring unsuspected tumors; such individuals may be asymptomatic.

Chapter 575 - Adrenal Masses

575.1 Adrenal Incidentaloma

As a result of the widespread use of CT and MRI, adrenal masses are discovered with increasing frequency in patients undergoing abdominal imaging for reasons unrelated to the adrenal gland. The rate of detection of single adrenal masses has ranged from less than 1% to more than 4% of abdominal CT examinations in adults. The unexpected discovery of such a mass presents the clinician with a dilemma in terms of diagnostic steps to undertake and treatment interventions to recommend. The differential diagnosis of adrenal incidentaloma includes benign lesions such as cysts, hemorrhagic cysts, hematomas, and myelolipomas. These lesions can usually be identified on CT or MRI. If the nature of the lesion is not readily apparent, additional evaluation is required. Included in the differential diagnosis of lesions requiring additional evaluation are benign adenomas, pheochromocytomas, adrenocortical carcinoma, and metastasis from an extra-adrenal primary carcinoma. Benign hormonally inactive adrenocortical adenomas comprise the majority of incidentalomas. Careful history, physical examination, and endocrine evaluation must be performed to seek evidence of autonomous cortisol, androgen, mineralocorticoid, or catecholamine secretion. Functional tumors require removal. If the adrenal mass is nonfunctional and larger than 6?cm, recommendations are to proceed with surgical resection of the mass. A recent recommendation has been made of 4?cm diameter as the threshold for removal. Lesions of 3?cm or less should be followed clinically with periodic re-imaging. Treatment, however, must be individualized; nonsecreting adrenal incidentalomas may enlarge and become hyperfunctioning. Nuclear scan, and occasionally fine-needle aspiration, may be helpful in defining the mass.

575.2 Adrenal Calcification

Calcification within the adrenal glands may occur in a wide variety of situations, some serious and others of no obvious consequence. Adrenal calcifications are often detected as incidental findings in radiographic studies of the abdomen in infants and children. The physician may elicit a history of anoxia or trauma at birth. Hemorrhage into the adrenal gland at or immediately after birth is probably the most common factor that leads to subsequent calcification. Although it is advisable to assess the adrenocortical reserve of such patients, there is rarely any functional disorder.

Neuroblastomas, ganglioneuromas, cortical carcinomas, pheochromocytomas, and cysts of the adrenal gland may be responsible for calcifications, particularly if hemorrhage has occurred within the tumor. Calcification in such lesions is almost always unilateral.

In the past, tuberculosis was a common cause both of calcification within the adrenals and of Addison disease. Calcifications may also develop in the adrenal glands of children who recover from the Waterhouse-Friderichsen syndrome; such patients are usually asymptomatic. Infants with *Wolman disease*, a rare lipid disorder due to deficiency of lysosomal acid lipase, have extensive bilateral calcifications of the adrenal glands (see Chapter 75.2).

Section 5 - *Disorders of the Gonads*

Robert Rapaport

Chapter 576 - Development and Function of the Gonads

Embryonic Gonadal Differentiation.

The undifferentiated, bipotential fetal gonad arises from a thickening of the urogenital ridge, close to the region that forms the kidney and adrenal cortex. At 6 wk of gestation, the gonad contains germ cells, stromal cells that will become Leydig cells in testes, or theca, interstitial or hilar cells in the ovary, and supporting cells that will develop into Sertoli cells in testes or granulosa cells in ovaries. In the absence of a testis-determining factor, thought to be the SRY (sex-determining region on the Y chromosome), the gonad develops into an ovary.

A 46,XX complement of chromosomes is necessary for the development of normal ovaries. Both the long and the short arms of X chromosomes bear genes for normal ovarian development. The *DSS* (dosage sensitive/sex reversal) locus associated with the *DAX1* gene responsible for X-linked congenital adrenal hypoplasia and hypogonadotropic hypogonadism, a member of the nuclear receptor superfamily, acts as a repressor of male gene expression. *DAX1* acts by binding to a related nuclear receptor SF-1 (steroidogenic factor-1). The signaling gene *WNT4* in vitro upregulates *DAX1*, resulting in enhanced interference with Leydig cell formation. WNTs are secreted ligands that activate receptor-mediated signal transduction pathways and are involved in modulating gene expression as well as cell behavior, adhesion, and polarity. Alternative splicing of the Wilms tumor 1 *(WT1)* gene may also be involved in sex differentiation. *WT1* mutations are associated with the Dennis-Drash syndrome (early-onset renal failure with abnormal external genitalia and Wilms tumor). Haploinsufficiency of a 3-amino acid (KTS) form

of *WT1* has been implicated in the gonadal dysgenesis of patients with Fraser syndrome (late-onset progressive glomerulopathy and 46,XY gonadal dysgenesis).

Autosomal genes also play a role in normal ovarian organogenesis and testicular development. Several conditions of gonadal dysgenesis are associated with chromosomal abnormalities. A deletion affecting the short arm of the X chromosome produces the typical somatic anomalies of Turner syndrome.

Development of the testis requires a Y chromosome, but the short arm of the Y chromosome is critical for sex determination; a testis-determining factor at this site has been identified, and the gene for it has been cloned and designated *SRY*. During male meiosis, the Y chromosome must segregate from the X chromosome so that both X and Y chromosomes do not occur in the same spermatozoa. The major portion of the Y chromosome is composed of Y-specific sequences that do not pair with the X chromosome. However, a minor portion of the Y chromosome shares sequences with the X chromosome and pairing does occur in this region. The genes and sequences in this area recombine between the sex chromosomes, behaving like autosomal genes. Therefore, the term *pseudoautosomal* is used to describe the genetic behavior of these genes. The *SRY* gene is localized to the 35-kb portion proximal to this pairing and exchange (pseudoautosomal) region of the Y chromosome. It contains a high-mobility group nonhistone protein (HMG box), suggesting that *SRY* may be a transcriptional regulator of other, some as yet unidentified, genes involved in sex differentiation. These include *SOX9*, an *SRY*-related gene, containing a shared motif homologous with the high-mobility group box 9 (HMG box 9) of *SRY*, located on chromosome 17, that results in sex reversal and campomelic dysplasia, steroidogenic factor 1 (SF-1) on chromosome 9q33, and the Wilms tumor genes *(WTI)* especially the -KSTiso form on chromosome 11p13 needed for early gonadal, adrenal, and renal development, fibroblast growth factor-9 (FGF-9), GATA-4, and XH-2. When recombination events extend beyond the pseudoautosomal region, X- and Y-specific DNA may be transferred between the chromosomes. Such aberrant recombinations result in X chromosomes carrying SRY, resulting in XX males, or Y chromosomes that have lost SRY, resulting in XY females. SRY acts as a transcriptional regulator to increase cellular proliferation, attract interstitial cells from adjacent mesonephros into the genital ridge and stimulates Sertoli cell differentiation. Sertoli cells act as organizer of steroidogenic and germ cell lines and produce anti-müllerian hormone (AMH) that causes the female duct system to regress.

Function of the Testes.

In the 1st trimester of pregnancy, levels of placental chorionic gonadotropin peak (8–12 wk) and stimulate the fetal Leydig cells to secrete testosterone, the main hormonal product of the testis. This period is critical for normal virilization of the XY fetus. Defects in this process lead to different forms of male pseudohermaphroditism (see Chapter 582.2). After virilization occurs, fetal levels of testosterone decrease but are maintained at low levels in the latter half of pregnancy by luteinizing hormone (LH) secreted by the fetal pituitary; this is required for continued penile growth.

As part of the normal transition from intrauterine to extrauterine life, likely as a result of the abrupt withdrawal of maternal and placental hormones, the newborn experiences a transient postnatal surge of gonadotropins and sex steroids. In males, LH and testosterone peak at 1–2 mo of age and reach prepubertal levels by 4–6 months of age. Follicle-stimulating hormone (FSH), along with inhibin B peak at 3 mo and decline to prepubertal levels by 9 and 15 mo, respectively. The LH rise is, however, dominant. In females, the FSH surge predominates. FSH peaks around 3–6 mo of age, declines by 12 mo, but remains detectable for 24 mo. Under LH influence, estradiol peaks at 2–6 mo of age. The inhibin B response is variable, peaking between 2–12 mo and remaining at above prepubertal levels until 24 mo. The neonatal surge may be important for postnatal maturation of the gonads, stabilization of male external genitalia, and perhaps also for gender identity and sexual behaviors. The postnatal surge in LH and testosterone is absent or blunted in infants with hypopituitarism, cryptorchidism, and complete androgen insensitivity syndrome (CAIS). The development of nocturnal pulsatile secretion of LH marks the advent of puberty (see Chapter 555).

Within specific target cells, 6–8% of testosterone is converted by 5-reductase to dihydrotestosterone, another potent androgen (see Fig. 582–1) and about 0.3% is acted on by aromatase to produce estradiol (see Fig. 568–1). Approximately half of circulating testosterone is bound to *sex hormone-binding globulin* (SHBG) and half to albumin; only 2% circulates in the free form. Plasma levels of SHBG are low at birth, rise rapidly during the 1st 10 days of life, and then remain stable until the onset of puberty. Thyroid hormone may play a role in this physiologic increase because neonates with athyreosis have very low levels of SHBG.

Anti-müllerian hormone (AMH, previously referred to as müllerian inhibitory substance [MIS]), inhibin, and activin are members of the transforming growth factor-ß (TGF-ß) superfamily of growth factors, which has over 45 members, including bone morphogenic proteins (BMPs). Members of the TGF-ß superfamily are involved in the regulation of developmental processes and multiple human disease states, including chondrodysplasias and cancer.

AMH, a 140-kd homodimeric glycoprotein hormone, is the earliest secreted product of the Sertoli cells of the fetal testis. Produced as a prohormone, its carboxyl-terminal fragment needs to be removed before it is active by way of a plasma membrane receptor. The gene for AMH is on chromosome 19. Its transcription is initiated by SOX-9 acting through the HMG box while its expression is upregulated by SF-1 binding to its promoter and further interacting with SOX-9, WT-I, and GATA-4. Two distinct serine/threonine receptors with a single transmembrane domain have been identified. The activated type 1 receptor signals to the SMAD family of intracellular mediators.

The gene for the AMH receptor (on chromosome 12) is expressed in Sertoli cells and also in fetal müllerian duct and fetal and postnatal granulosa cells. During sexual differentiation, AMH causes involution of the embryologic precursors of the cervix, uterus, and fallopian tubes (müllerian ducts).

AMH is secreted in males by Sertoli cells during both fetal and postnatal life. In females, it is secreted by granulosa cells from 36 wk of gestation to menopause but at lower levels. The serum concentration of AMH in males is highest at birth, whereas in females it is highest at puberty. After puberty, both sexes have similar serum concentrations of AMH.

Inhibin is another glycoprotein hormone secreted by the Sertoli cells of the testes and granulosa and theca cells of the ovary. Inhibin A consists of an a-subunit disulfide linked to the ß A subunit, whereas inhibin B consists of the same a subunit linked to the ß B subunit.

Activins are dimers of the B subunits, either homodimers (BA/BA, BB/BB) or heterodimers (BA/BB). Inhibins selectively inhibit whereas activins stimulate pituitary FSH secretion. By means of immunoassays specific for inhibin A or B, it has been shown that inhibin A is absent in males and is present mostly in the luteal phase in women. Inhibin B is the principal form of inhibin in males and females during the follicular phase. Inhibin B may be used as a marker of Sertoli cell function in males. FSH stimulates inhibin B secretion in females and males, but only in males is there also evidence for a gonadotropin-independent way of its regulation.

Like inhibin and activin, follistatin (a single-chain glycosylated protein) is produced by gonads and other tissues such as the hypothalamus, kidney, adrenal gland, and placenta. Follistatin inhibits FSH secretion principally by binding activins,

thus blocking the effects of activins at the level of both ovary and pituitary.

An additional plethora of peptides are known to be involved as mediators of the development and function of the testis. They include neurohormones such as growth hormone–releasing hormone, gonadotropin-releasing hormone (GnRH), corticotropin-releasing hormone, oxytocin, arginine vasopressin, somatostatin, substance P, and neuropeptide Y; growth factors such as insulin-like growth factors (IGFs) and IGF-binding proteins, TGF-ß, and fibroblast, platelet-derived, and nerve growth factors; vasoactive peptides; and immune-derived cytokines such as tumor necrosis factor and interleukins IL-1, IL-2, IL-4, and IL-6.

Considerable attention will continue to be focused on the complex endocrine and, especially, paracrine, autocrine, and intracrine effects of these regulatory peptides.

Clinical patterns of pubertal changes vary widely (see Chapters 14 and 555). In 95% of boys, enlargement of the genitals begins between 9.5 and 13.5 yr, reaching maturity from 13–17 yr. In a minority of normal boys, puberty begins after 15 yr of age. In some boys, pubertal development is completed in less than 2 yr, but in others, it may take longer than 4.5 yr. The adolescent growth spurt occurs later in boys than in girls at corresponding levels of sexual maturation; for example, the peak velocity of change in height is not attained in boys until the genitals are well developed, but in girls the growth rate is usually at its maximum when the nipple and areola have developed but before there is any other significant breast development.

The median age of sperm production *(spermarche)* is 14 yr. This event occurs in mid puberty as judged by pubic hair, testis size, evidence of growth spurt, and testosterone levels. Nighttime levels of FSH are in the adult male range at the time of spermarche; the first conscious ejaculation occurs at about the same time.

Function of the Ovaries.

Without the presence of the *SRY* gene, the undifferentiated gonad can be identified histologically as an ovary by 10–11 wk of gestation. Oocytes are present from the 4th mo of gestation and reach a peak of 7 million by 5 mo of gestation. For normal maintenance, oocytes need granulosa cells to form primordial follicles. Functional FSH (but not LH) receptors are present in oocytes of primary follicles during follicular development. Normal X chromosomes are needed for the maintenance of the oocytes. In contrast to somatic cells, in which only one X chromosome is active, both are active in germ cells. At birth, the ovaries contain about 1 million active follicles, which decrease to 0.5 million by menarche. Thereafter, they decrease at a rate of 1000/mo, and at an even higher rate after the age of 35 yr.

The hormones of the fetal ovary are provided in most part by the fetoplacental unit. As in males, peak gonadotropin secretion occurs in fetal life and then again at 2–3 mo of life, with the lowest levels at about 6 yr of age. In both infancy and childhood, gonadotropin levels are higher in females than in males.

The most important estrogens produced by the ovary are estradiol-17 (E_2) and estrone (E_1); estriol is a metabolic product of these two, and all three estrogens may be found in the urine of mature females. Estrogens also arise from androgens in the adrenal gland and in the testis; the pathway for this conversion is shown in Figure 568–1 . This conversion explains why in certain types of male pseudohermaphroditism, feminization occurs at puberty; in 17-ketosteroid reductase deficiency, for example, the enzymatic block results in markedly increased secretion of androstenedione, which is converted in the peripheral tissues to estradiol and estrone; these estrogens, in addition to those directly secreted by the testis, result in gynecomastia. Estrogen regulates a host of functionally different activities in multiple tissues. There are two distinct estrogen receptors with different expression patterns. The ovary also synthesizes progesterone, a progestational steroid; the adrenal cortex and testis synthesize progesterone as a precursor for other adrenal and testicular hormones.

As in the testis, a host of other hormones with autocrine, paracrine, and intracrine effects have been identified in the ovary. They include inhibins, activins, relaxin, and growth factors IGF-1, TGF-a and TGF-ß, and cytokines.

Plasma levels of estradiol increase slowly but steadily with advancing sexual maturation and correlate well with clinical evaluation of pubertal development, skeletal age, and rising levels of FSH. Levels of LH do not rise until secondary sexual characteristics are well developed. Estrogens, like androgens, inhibit secretion of both LH and FSH (negative feedback). In females, estrogens also provoke the surge of LH secretion that occurs in the mid-menstrual cycle. The capacity for this positive feedback is another maturational milestone of puberty.

The average age at menarche in American girls is 12.5–13 yr, but the range of “normal” is wide, and 1–2% of “normal” girls have not menstruated by 16 yr of age. The age at onset of pubertal signs varies, with recent studies suggesting earlier ages then previously thought, especially in the United States African American population (see Chapter 14). Menarche generally correlates closely with skeletal age (see Chapters 14 and 555). Maturation and closure of the epiphyses is at least partially estrogen dependent, as demonstrated by a 28-yr-old, normally masculinized male with incomplete closure of the epiphyses who proved to have complete estrogen insensitivity because of an estrogen-receptor defect.

Diagnostic Aids.

Improved, sensitive, and specific assays for pituitary and gonadal hormones that can be measured in small amounts of blood have contributed to rapid advances in the understanding of normal and aberrant hypothalamic-pituitary-gonadal interactions. For example, in male infants, measurements of LH, FSH, and testosterone can detect pituitary-testicular defects. Leydig cell integrity in childhood can be determined by the testosterone response following human chronic gonadotropic administration (e.g., 5,000?IU daily for 3 days). The integrity as well as the maturity of the hypothalamic-pituitary-gonadal axis in males and females can be assessed by the administration of gonadotropin-releasing hormone (GnRH) or a GnRH analog. An ultrasensitive LH assay has been shown to differentiate between boys with delayed puberty and those with complete but not partial hypogonadotropic hypogonadism.

Normal inhibin B levels have been documented in infant boys; inhibin B may be a marker of spermatogenesis and also of tumors such as granulosa cell tumors. Inhibin may be involved in tumor suppression. Estrogen-receptor assays may be clinically useful in the management of various ovarian cancers. AMH measurements are useful in the evaluation of children with nonpalpable gonads and intersex problems.

Therapeutic Aids.

Phytoestrogens, a family of plant compounds such as soy and flax products, have been shown to have both estrogenic and antiestrogenic properties. Their potential health consequences, so far based largely on population studies, are being investigated. Polyhalogenated aromatic hydrocarbons (PHAHs) are environmental pollutants acting as endocrine disruptors by interfering with reproductive and endocrine function in birds, fish, reptiles, and mammals. The estrogenic effects of PHAHs may in part be due to inhibition of estradiol sulfation by estrogen sulfotransferase (SULTIE), an important pathway of estradiol inactivation. Naturally occurring estrogens administered orally are rapidly destroyed by gastrointestinal and liver enzymes; accordingly, they are usually given as conjugates or esters. The most widely used oral preparations are equine conjugated estrogens (e.g., Premarin) and ethinyl estradiol. Estrogen-containing skin patches for

transdermal absorption are also used. With improvements in the understanding of estrogen and estrogen receptor interactions, a new class of compounds called selective estrogen-receptor modulators have been synthesized. For example, raloxifene, a nonsteroidal benzothiophene derivative acts as an estrogen agonist in bone and liver and as an estrogen antagonist in breast and uterus. Androgens such as testosterone are generally injected intramuscularly as long-acting esters (enanthate or cypionate, most commonly) because of their potency and steady response. Transdermal testosterone patches applied to the scrotal or nonscrotal areas and a cutaneously applied gel have to date been used mostly in adults with hypogonadism because of the difficulty in titrating the doses needed during childhood and adolescence. Oral preparations, such as methyltestosterone or fluoxymesterone, do not produce as potent an androgenic response and may be hepatotoxic. Testosterone undecenoate, another oral preparation, is used in Europe but not in the United States. Sublingual (microspheres or pellets) and buccal (absorption via the buccal mucosa) preparations of testosterone are in development.

Chapter 577 - Hypofunction of the Testes

Testicular hypofunction may be primary in the testis (primary hypogonadism) or secondary to deficiency of pituitary gonadotropic hormones (secondary hypogonadism). Patients with primary hypogonadism have elevated levels of gonadotropin (hypergonadotropic); those with secondary hypogonadism have low or absent levels (hypogonadotropic).

577.1 Hypergonadotropic Hypogonadism in the Male (Primary Hypogonadism)

Defects of androgen production involving the fetal testis and resulting in male pseudohermaphroditism are discussed in Chapter 582.1 .

Etiology.

Congenital anorchia occurs in 0.6% of boys with nonpalpable testes (1/20,000 males). These boys have normal external genitals, indicating that a noxious factor damaged the fetal testes of the genetic male fetus at some time after sexual differentiation had taken place (14th wk of fetal life). Hence, some refer to this condition as *vanishing testes syndrome.* The condition has been reported in monozygotic twins. Familial occurrence of this condition suggests a genetic etiology. Low levels of testosterone (<10?ng/dL) and markedly elevated levels of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) are found in the early postnatal months; thereafter, levels of gonadotropins tend to decrease even in agonadal children, rising to very high levels as the pubertal years approach. Stimulation with human chorionic gonadotropin (hCG) fails to evoke an increase in the levels of testosterone. Serum levels of anti-müllerian hormone (AMH) are undetectable or low.

A syndrome of *rudimentary testes* has been described in which the testes are exceedingly small; this appears to be inherited as an autosomal or X-linked recessive trait. The cause is unknown. Atrophy of the testes may follow damage to the vascular supply as a result of unskillful manipulation of the testes during surgical procedures for correction of cryptorchidism or as a result of bilateral torsion of the testes. Acute orchitis in pubertal or adult males with mumps may also damage the testes; usually, only the reproductive function of the testes is impaired. The routine immunization of all prepubertal males with mumps vaccine should prevent this complication.

Testicular damage is a frequent consequence of chemotherapy and radiotherapy for cancer. The frequency and extent of damage depend on the agent used, total

dosage, duration of therapy, and post-therapy interval of observation. Another important variable is age at therapy; germ cells are less vulnerable in prepubertal than in pubertal and postpubertal boys. Chemotherapy is most damaging if more then one agent is used. The use of alkylating agents such as cyclophosphamide in prepubertal children does not impair pubertal development, even though there may be biopsy evidence of germ cell damage. Most chemotherapeutic agents produce azoospermia and infertility more commonly then Leydig cell damage. Interleukin-2 can depress Leydig cell function, whereas interferon-a does not seem to affect gonadal function.

Radiation damage is dose dependent (see Chapter 700). Temporary azoospermia can be seen with doses greater then 0.3?Gy, with permanent azoospermia seen with doses greater then 8?Gy. Leydig cells are more resistant to radiation. Mild damage as determined by elevated LH levels can be seen with up to 6?Gy;

---

doses greater then 30?Gy cause hypogonadism in most. Whenever possible, testes should be shielded from radiation. Testicular function should be carefully evaluated in adolescents after multimodal treatment for cancer in childhood. Replacement therapy with testosterone and counseling concerning fertility may be indicated.

The term *hypogonadism* has been widely used to describe aspects in children with a variety of multiple malformation syndromes. The term often refers simply to cryptorchidism, a small phallus, or a scrotal anomaly. In many of these syndromes little is known about the function of the testes; hypergonadotropic or hypogonadotropic hypogonadism has been proved in some instances.

In patients with *Prader-Willi syndrome*, both hypogonadotropic hypogonadism and hypergonadotropic hypogonadism, perhaps secondary to cryptorchidism and its treatment, have been reported. Growth hormone treatment has resulted in improved body composition, physical and psychomotor function, as well as growth in patients with Prader-Willi syndrome. Small testes and azoospermia are seen in patients with the *Sertoli cell-only syndrome* (germ cell aplasia or Del Castillo syndrome).

Various degrees of hypogonadism also occur in a significant percentage of patients with chromosomal aberrations such as Klinefelter syndrome or XX males.

Clinical Manifestations.

Primary hypogonadism may be suspected at birth if the testes and penis are abnormally small. The condition often is not noticed until puberty when secondary sex characteristics fail to develop. Facial, pubic, and axillary hair is scant or absent; there is neither acne nor regression of scalp hair; and the voice remains high pitched. The penis and scrotum remain infantile and may be almost obscured by pubic fat; the testes are small or absent. Fat accumulates in the region of the hips and buttocks and sometimes in the breasts and on the abdomen. The epiphyses close late in life; therefore, extremities are long. The span is several inches longer than the height, and the distance from the symphysis pubis to the soles of the feet is much greater than that from the symphysis to the vertex. The proportions of the body are described as *eunuchoid*. (The upper to lower segment ratio is considerably less than 0.9.) Many individuals with milder degrees of hypogonadism may be detected only by appropriate studies of the pituitary-gonadal axis. Examination of the testes should be performed routinely by pediatricians; testicular volumes as determined by comparison with standard orchidometers should be recorded.

Diagnosis.

Levels of serum FSH and, to a lesser extent, of LH are elevated to greater than age-specific normal values. These elevated levels indicate that even in the prepubertal child there is an active hypothalamic-gonadal feedback relationship. After the age of 11 yr, FSH and LH levels rise significantly, reaching the castrate range. Measurements of random plasma testosterone levels in prepubertal boys are not helpful because they are ordinarily low in normal prepubertal children, rising during puberty to attain adult levels. During puberty, these levels correlate better with testicular size, stage of sexual maturity, and bone age than with chronologic age. In patients with primary hypogonadism, testosterone levels remain low at all ages. There is an attenuated rise or no rise after administration of hCG, in contrast to normal males in whom hCG produces a significant rise in plasma testosterone at any stage of development. Measurements of serum AMH and inhibin levels may give an indication of gonadal presence and function.

NOONAN SYNDROME

Etiology.

The term *Noonan syndrome* has been applied to males and females who have certain phenotypic features that occur also in females with Turner syndrome. These boys and girls have normal karyotypes. Noonan syndrome occurs in 1:1000–2500 live births. The disorder is autosomal dominant with variable expression. Sporadic and autosomal recessive occurrence has been reported. Missense mutations in *PTPN11*—a gene on chromosome 12q24.1 encoding the nonreceptor protein tyrosine phosphatase SHP-2—are seen in the majority of studied cases.

Clinical Manifestations.

The most common abnormalities are short stature, webbing of the neck, pectus carinatum or pectus excavatum, cubitus valgus, right-sided congenital heart disease, and characteristic facies. Hypertelorism, epicanthus, downward slanted palpebral fissures, ptosis, micrognathia, and ear abnormalities are common. Other abnormalities such as clinodactyly, hernias, and vertebral anomalies occur less frequently. The mean IQ of school-aged children with the condition is 86, with a range of 53 to 127. Verbal IQ tends to be better than performance IQ. High-frequency sensorineural hearing loss is common. The cardiac defect is most often pulmonary valvular stenosis, hypertrophic cardiomyopathy, or atrial septal defect. Hepatosplenomegaly and several hematologic diseases, including low clotting factors XI and XII, acute lymphoblastic leukemia, and chronic myelomonocytic leukemia, are noted. Features of both Noonan syndrome and type 1 neurofibromatosis have been reported, but linkage has been excluded. Noonan-like features can be part of the phenotypic variation of the *NF1* gene mutation, suggesting the possible existence of a Noonan syndrome locus also on chromosome

17q. A few patients with *NF1* and features of Noonan syndrome were subsequently reported as having Turner syndrome. Males frequently have cryptorchidism and small testes; they may be hypogonadal or normal. Puberty is delayed 2 yr; adult height is achieved by the end of the 2nd decade and usually reaches the lowest limit of the normal population. Prenatal diagnosis should be suspected in fetuses with normal karyotype, edema, or hydrops and short femur length.

Treatment.

Human growth hormone has resulted in improvement in growth velocity comparable to that seen in patients with Turner syndrome without adverse effects on cardiac ventricular wall thickness. Adult height after growth hormone treatment, resulting in improved height, has only been reported in fewer than 12 patients.

KLINEFELTER SYNDROME

Also see Chapters 70 and 554 .

Etiology.

Approximately 1/500 newborn males has a 47,XXY chromosome complement, representing the most common sex chromosomal aneuploidy in males. The incidence approximates 1% among the mentally retarded, clustering among patients with IQs greater than 50 and among children admitted to psychiatric hospitals or referred to psychiatric clinics. In infertile males, the incidence is 3%. The chromosomal aberration most often results from meiotic nondisjunction of an X chromosome during parental gametogenesis; the extra X chromosome is maternal in origin in 54% and paternal in origin in 46% of patients. Increased maternal age predisposes to meiotic nondisjunction and to this syndrome, but in most instances maternal age is not advanced.

The 47,XXY complement is the most common chromosomal pattern in persons with Klinefelter syndrome (80%); some have mosaic patterns: 46,XY/47,XXY, 46,XY/48,XXYY, 45,X/46,XY/ 47,XXY, or 46,XX/47,XXY. Rarely, occurrence of more than two X chromosomes may result in Klinefelter variants: 48,XXXY, 49,XXXYY, 49,XXXXY, 50,XXXXYY, 47,XXY/48,XXXY, 47,XXY/ 49,XXXXY, or 48,XXYY karyotype. Even with as many as four X chromosomes, the Y chromosome determines a male phenotype. In most patients with four or five X chromosomes, all the additional chromosomes come from the same parent and are not associated with increased parental age.

Clinical Manifestations.

The diagnosis is rarely made before puberty because of the paucity or subtleness of clinical manifestations in childhood. Because behavioral or psychiatric disorders may often be apparent long before defects in sexual development, the condition should be considered in all boys with mental retardation and in children with psychosocial, learning, or school adjustment problems. Affected children may be anxious, immature, excessively shy, or aggressive, and they may engage in antisocial acts. Fire-setting behavior has been observed in some of these children. In a prospective study, a group of children with 47,XXY karyotypes identified at birth exhibited relatively mild deviations from normal during the first 5 yr of life. None had major physical, intellectual, or emotional disabilities; some were inactive, with poorly organized motor function and mild delay in language acquisition. Problems often first become apparent after the child begins school. Full-scale IQ scores may be normal, with verbal IQ being somewhat decreased. Verbal cognitive defects and underachievement in reading, spelling, and mathematics are common. By late adolescence, most boys with Klinefelter syndrome have generalized learning disabilities, most of which are language based, and are four to five grade levels behind. Despite these difficulties, most complete high school. High-resolution MRI has shown reduction in left temporal lobe gray matter volumes (less so in testosterone-treated subjects).

The patients tend to be tall, slim, and underweight and to have relatively long legs, but body habitus can vary markedly. The testes tend to be small for age, but this sign may become apparent only after puberty, when normal testicular growth fails to occur. The phallus tends to be smaller than average, and cryptorchidism or hypospadias may occur in a few patients.

Pubertal development may be delayed. Some degree of androgen deficiency is usually detected, although some children may undergo almost normal virilization. About 80% of adults have gynecomastia; they have sparser facial hair, most shaving less often than daily. The most common testicular lesions are spermatogenic arrest and Sertoli cell predominance. The sperm have a high incidence of sex chromosomal aneuploidy. Azoospermia and infertility are usual, although rare instances of fertility are known. Testicular sperm extraction followed by intracytoplasmic sperm injection can result in the birth of healthy infants. Antisperm antibodies have been detected in one quarter of tested specimens. In nonmosaic Klinefelter patients, most testicular sperm (94%) have a normal pattern of sex chromosome segregation.

The height of patients with Klinefelter syndrome tends to be increased. There is an increased incidence of pulmonary disease, varicose veins, and cancer of the breast. Among 93 unselected male breast cancer patients, 7.5% were found to have Klinefelter syndrome. Mediastinal germ cell tumors have been reported; some of these tumors produce hCG and cause precocious puberty in young boys. They may also be associated with leukemia, lymphoma, and other hematologic neoplasia. The highest cancer risk (relative risk 2.7) occurs in the 15–30 yr age group.

In adults with XY/XXY mosaicism, the features of Klinefelter syndrome are decreased in severity and frequency. Children with mosaicism have a better prognosis for virilization, fertility, and psychosocial adjustment.

KLINEFELTER VARIANTS.

When the number of X chromosomes exceeds two, the clinical manifestations, including mental retardation and impairment of virilization, are more severe. The XXYY variant is the most common variant (1/50,000 male births). In most, mental retardation occurs with IQ scores between 60 and 80, but 10% have IQs greater then

110. The XXYY male phenotype is not distinctively different from that of the XXY patient, except that XXYY adults tend to be taller than the average XXY patient. The 49,XXXXY variant is sufficiently distinctive to be detected in childhood. Its incidence is estimated to be 1/80,000 to 1/100,000 male births. The disorder arises from sequential nondisjunction in meiosis. Affected patients are severely retarded and have short necks and typical coarse facies with wide-set eyes with a mild upward slant of the fissures, epicanthus, strabismus, a wide and flat upturned nose, a large open mouth, and large malformed ears. The testes are small and may be undescended, the scrotum is hypoplastic, and the penis is very small. Defects suggestive of Down syndrome (e.g., short incurved terminal 5th phalanges, single palmar creases, and hypotonia) and other skeletal abnormalities (including defects in the carrying angle of the elbows and restricted supination) are common. The most frequent radiographic abnormalities are radioulnar synostosis or dislocation, elongated radius, pseudoepiphyses, scoliosis or kyphosis, coxa valga, and retarded osseous age. Most patients with such extensive changes have a 49,XXXXY chromosome karyotype; several mosaic patterns have also been observed: 48,XXXY/49,XXXXY (Fig. 577–1); 48,XXXY/49,XXXXY/50,XXXXXY; and 48,XXXY/49,XXXXY/50, XXXXYY. Prenatal diagnosis of a 49,XXXXY infant has been reported. The fetus had intrauterine growth retardation, edema, and cystic hygroma colli.

The 48,XXXY variant is relatively rare. The characteristic features are generally less severe then in those patients with 49,XXXXY and more severe than in 47,XXY patients. Mild mental retardation, delayed speech and motor development, and immature but passive and pleasant behavior are associated with this condition.

Very few patients have been described with 49,XYYY and 49,XXYYY karyotypes. Dysmorphic features and mental retardation are common to both.

Laboratory Findings.

Most males with this condition go through life undiagnosed. The chromosomes should be examined in all patients suspected of having Klinefelter syndrome, particularly

Figure 577.1-1 A 12-yr-old boy with 48,XXXY/49,XXXXY mosaicism who has prognathism, epicanthal folds, scoliosis, very small testes, severe mental retardation, clinodactyly, and radioulnar synostoses.

those attending child guidance, psychiatric, and mental retardation clinics. Before 10 yr of age, boys with 47,XXY Klinefelter syndrome have normal basal plasma levels of FSH and LH. Responses to gonadotropin-stimulating hormone and to hCG are also normal. The testes show normal growth early in puberty, but by mid puberty the testicular growth stops, gonadotropins become elevated, and testosterone levels are slightly low. Inhibin B levels are low in men with the syndrome. Elevated levels of estradiol, resulting in a high estradiol:testosterone ratio, account for the development of gynecomastia during puberty. Despite hypogonadism, most have normal bone mass.

Testicular biopsy before puberty may reveal only a deficiency or absence of germinal cells. After puberty, the seminiferous tubular membranes are hyalinized, and there is adenomatous clumping of Leydig cells. Sertoli cells predominate. Azoospermia is characteristic, and infertility is the rule.

Treatment.

Replacement therapy with a long-acting testosterone preparation depends on the age of the patient. It should begin at 11–12 yr of age. The enanthate ester may be used in a starting dose of 25–50?mg injected intramuscularly every 3–4 wk, with 50-mg increments every 6–9 mo until a maintenance dose for adults (200–250?mg every 3–4 wk) is achieved. At that time, testosterone patches or testosterone gel may be substituted for the injections. For older boys, larger initial doses and increments can achieve more rapid virilization. Testosterone treatment leads to an increase in prostate volume and prostate-specific antigen levels. Fertility can be accomplished by an intracytoplasmic sperm injection technique.

XX MALES

This disorder is thought to occur in 1 of 20,000 newborn males. Affected individuals have a male phenotype, small testes, a small phallus, and no evidence of ovarian or müllerian duct tissue; they appear, therefore, to be distinct from the XX true hermaphrodite (see Chapter 582.3). This disorder resembles Klinefelter syndrome, but stature is greater in the latter. Undescended testes and hypospadias occur in a minority of patients. The histologic features of the testes are essentially the same as in Klinefelter syndrome. Patients with the condition usually come to medical attention in adult life because of hypogonadism, gynecomastia, or infertility. Hypergonadotropic hypogonadism occurs secondary to testicular failure. A few cases have been diagnosed perinatally as a result of discrepancies between prenatal ultrasonography and karyotype findings.

In 80% of XX males with normal male external genitals, one of the X chromosomes carries the *SRY* gene. The exchange from the Y to the X chromosome occurs during paternal meiosis, when the short arms of the Y and X chromosomes pair. XX males inherit one maternal X chromosome and one paternal X chromosome containing the translocated male-determining gene. Such exchanges occur because of the proximity of the *SRY* gene to the pseudoautosomal region where recombination between X and Y chromosomes normally occurs in meiosis. Most XX males who are identified before puberty have hypospadias or micropenis; this group of patients usually lacks Y-specific sequences, suggesting other mechanisms for virilization (see Chapter 576). Fluorescent in situ hybridization and primed in situ labeling (PRINS) have been used to identify small *SRY* DNA segments. Yp fragment abnormalities may result in sexually ambiguous phenotypes.

45,X MALES

Also see Chapter 576 .

Of the few male patients recognized with a 45,X karyotype, Yp sequences have been translocated to an autosomal chromosome. In one instance, the terminal short

arm of the Y chromosome was translocated onto an X chromosome. In another, SRY/autosomal translocation was postulated. A male with 45,X karyotype and Leri-Weill dyschondrosteosis, *SHOX* gene loss, and *SRY* to Xp translocation was also described.

47,XXX MALES

A Japanese male with poor pubic hair development, hypoplastic scrotal testes (4?mL), normal penis and normal height, gynecomastia, and severe mental retardation had 47,XXX karyotype due to abnormal X-Y interchange during paternal meiosis and X-X nondisfunction during maternal meiosis.

XYY MALES

The 47,XYY male does not have hypogonadism; this condition is discussed here for easy comparison with the XXY and the XX male syndromes.

Approximately 1/1,000 male newborns has an XYY chromosome pattern. In most, the extra Y is generated by nondisjunction at meiosis II after a normal chiasmate meiosis I. When this disorder was first discovered in adults, studies of XYY individuals in mental or penal institutions created a stereotype of affected individuals as having deviant behavior marked by physical aggressiveness and violence. The rate at which XYY males are found in mental or penal settings may be 20 times higher than the rate of the condition of birth. Adults with this karyotype may be relatively impulsive, antisocial, and likely to break the law, but they are not especially aggressive. Unselected 47,XYY boys detected in screening programs tend to exhibit attention deficits, impulsive behavior, inadequate interactions, and poor self-image. Patients with 48,XXYY and 48,XYYY karyotypes tend to have similar deviant behavior.

The XYY adult has few phenotypic manifestations. He tends to be tall and to have severe nodulocystic acne. In affected persons, genital abnormalities have been observed, but cryptic mosaicism, such as X/XYY, is a possibility in these instances. Prolonged PR intervals on electrocardiography and radioulnar synostosis occur more often than in the general population. Renal agenesis and cystic dysplasia of the kidney, as well as hematologic malignancies, have been reported. No clear-cut endocrine abnormalities have been found. This condition poses a serious dilemma for counseling of parents of infants or children discovered to have this sex chromosome complement. The risks for some developmental disability may not be trivial, but neither do they appear to be as dire as earlier thought. Still, the most common reason for a 47,XYY male to be karyotyped is developmental delay or behavioral problems, or both. Children with sex chromosome abnormalities are at an increased risk of learning disabilities, cognitive skill impairments, and difficulties in psychosocial adaptation. Stable, supportive, and compassionate family environments promote improved adaptation of these children and adolescents.

577.2 Hypogonadotropic Hypogonadism in the Male (Secondary Hypogonadism)

In hypogonadotropic hypogonadism, there is deficiency of FSH or LH, or both. The primary defect may lie in the anterior pituitary or in the hypothalamus as a deficiency of gonadotropin-releasing hormone (GnRH). The testes are normal but remain in the prepubertal state because stimulation by gonadotropins is lacking. The disorder may be recognized in infancy, around the time of puberty, or, rarely, in adulthood. Several different gene defects have been described in patients with hypogonadotropic hypogonadism.

Etiology

HYPOPITUITARISM.

Most causes of hypopituitarism may be associated with deficiency of gonadotropins and hypogonadotropic hypogonadism (see Chapter 551). In patients with organic lesions in or near the pituitary, whether congenital or acquired, the gonadotropin deficiency is pituitary in origin. In most patients with “idiopathic” hypopituitarism, the defect is in the hypothalamus, caused by a deficiency of GnRH. In patients with multiple pituitary hormone deficiencies, defects in pituitary transcription factors such as PROP-1, HESX-1, and LHX-3 have been described. Microphallus (<2.5?cm) in the newborn male with growth hormone deficiency suggests the likelihood of gonadotropin deficiency, and diagnostic confirmation is feasible; after 6 mo of age, gonadotropin deficiency can rarely be established with certainty until the teenage years.

ISOLATED DEFICIENCY OF GONADOTROPIN.

Usually, this disorder involves the hypothalamus rather than the pituitary. It affects about 1/10,000 males and 1/50,000 females and encompasses a heterogeneous group of entities. GnRH deficiency may be complete or partial; it may occur sporadically or in families. *Kallmann syndrome,* one of the most frequent genetic forms of hypogonadotropic hypogonadism, is characterized by its association with anosmia or hyposmia. The X-linked disorder is caused by several mutations of the *KAL* gene at Xp22.3. The association reflects the failure of olfactory axons and GnRH-expressing neurons to migrate from their common origin in the olfactory placode to the brain. The *KAL* gene product anosmin-1, an extracellular matrix glycoprotein, facilitates neuronal growth and migration. The *KAL* gene is also expressed in various parts of the brain, facial mesenchyme, and mesonephros and metanephros, thus explaining some of the associated findings in patients with Kallman syndrome, and as synkinesia, midfacial defects, and renal agenesis.

Some kindreds contain anosmic individuals with or without hypogonadism; others contain hypogonadal individuals who are anosmic. Cleft lip and palate, hypotelorism, median facial clefts, sensorineural hearing loss, unilateral renal aplasia, neurologic deficits, and other findings occur in some affected patients. When Kallmann syndrome is caused by terminal or interstitial deletions of the Xp22.3 region, it may be associated with other contiguous gene syndromes, such as steroid sulfatase deficiency, chondrodysplasia punctata, X-linked ichthyosis, or ocular albinism. Autosomal recessive and autosomal dominant forms of Kallmann syndrome have been reported.

As in patients with Kallmann syndrome, children with *X-linked congenital adrenal hypoplasia* have associated hypogonadotropic hypogonadism (HHG) owing to impaired gonadotropin-releasing hormone (GnRH) secretion. In these patients, there is a mutation of the *DAX1* gene at Xp21.2-21.3. Conditions occasionally associated with these patients because of the contiguous gene syndrome include glycerol kinase deficiency, Duchenne muscular dystrophy, and ornithine transcarbamyl transferase deficiency. Most boys with *DAX1* mutations develop HHG in adolescence, although a patient with adult-onset adrenal insufficiency and partial HHG and two females with HHG and delayed puberty have also been described, the latter as part of extended families with males with classic HHG. The *DAX1* gene defect is, however, rare in patients with delayed puberty or HHG without at least a family history of adrenal failure.

Several genetic defects involving the hypothalamic-pituitary-gonadal axis have been identified. They involve the function of either hormones or their receptors. Depending on both the level and nature of the mutation, hypogonadism, precocious puberty, or sexual ambiguity may develop. To date, eight different GnRH-receptor gene mutations, most compound heterozygotes, have been identified as the cause of HHG. The phenotype, however, varies from partial to complete hypogonadism. A mutation in the gene for the ß-subunit of LH at the level of the pituitary causes HHG. At the level of the gonads, LH-receptor defects have led to Leydig cell hypoplasia and undervirilization in genetic males. A boy was reported with micropenis and normal testes that did not produce testosterone even after repeated courses of hCG. Vanishing Leydig cell syndrome was thought to be a possibility (by analogy with the vanishing testes syndrome). Normally functioning Leydig cells must have been present in the first trimester of pregnancy, but because of LH receptor defect, inadequate testosterone production in the 2nd and 3rd trimesters led to an underdeveloped penis at birth. A novel mutation of the ß-subunit of FSH also has been described as the cause of hypogonadism in an 18-yr-old man evaluated for delayed puberty and three women with delayed puberty and primary amenorrhea (Table 577–1). Mutations in leptin, in the leptin receptor as well as in the endopeptidase prohormone convertase-1 (PC-1), have been associated with HHG.

OTHER DISORDERS.

HHG has been observed in a few patients with polyglandular autoimmune syndrome, in some with elevated melatonin levels, and in a variety of other syndromes, such as Bardet-Biedl, Prader-Willi, multiple lentigines, and several syndromes of ataxia.

Diagnosis.

Levels of gonadotropins and gonadal steroids remain in the prepubertal range, and nocturnal pulsatile secretion of LH does not occur. The gonadotropin response to stimulation with GnRH or a more potent analogue of GnRH is markedly blunted. These findings are also consistent with those observed in normal adolescents with the variant known as constitutional delayed puberty; it is difficult to distinguish between the two conditions. Many different tests, including stimulation tests with GnRH, thyrotropin-releasing hormone, metoclopramide, and domperidone, have yielded inconclusive results. The measurement of a single, 8 am testosterone level may be a good indicator of impending puberty. A value of more then 0.7?nmol/L (20?mg/dL) was noted in boys, all of whom had an increase in testicular volume to greater than 4?mL by 15 mo and 77% by 12 mo. In contrast, of boys with testosterone levels lower then 0.7?nmol/L, only 25% entered puberty by 15 yr of age. The use of a GnRH analogue or the GnRH test after 36?hr of “priming” of the hypothalamic-pituitary-gonadal axis with pulsatile GnRH administration may distinguish adolescents with hypogonadism from those with delayed puberty.

Gonadotropin deficiency is likely if the patient has evidence of another pituitary deficiency, such as a deficiency of growth hormone, particularly if it is associated with corticotropin (adrenocorticotropic hormone [ACTH]) deficiency. The presence of

TABLE 577.2-1 -- Known Gene Defects Causing Hypogonadism

Defect	Clinical Condition	Affected Gender
Gonadotropin-Releasing Hormone		
KAL-1	Kallmann syndrome	Both
DAX-1	X-linked adrenal hypoplasia and hypogonadotropic hypogonadism	Male
Receptor	Familial hypogonadotropic hypogonadism	Both
Luteinizing Hormone		
ß Subunit	Pubertal delay, Leydig cell hypoplasia, infertility	Male
Receptor	Male pseudohermaphroditism, Leydig cell hypoplasia, micropenis	Both
	Amenorrhea	
Follicle-Stimulating Hormone		
ß Subunit	Pubertal delay	Both
	Amenorrhea	
Receptor	Ovarian failure	Female
	Ovarian germ cell tumors	

anosmia usually indicates permanent gonadotropin deficiency, but occasional

instances of markedly delayed puberty (18–20 yr of age) have been observed in anosmic individuals. Although anosmia may be present in the family or in the patient from early childhood, its existence is rarely volunteered, and direct questioning is necessary in all patients with delayed puberty. MRI may detect anomalous olfactory lobes and sulci in some patients. Prolactinomas are increasingly recognized as a cause of delayed puberty and should be excluded by determination of serum levels of prolactin.

Probes are available to establish the diagnosis in heterozygotes and newborn infants with the X-linked form of Kallmann syndrome. During the first 3–4 mo of life, unaffected infants demonstrate the usual physiologic rise in gonadotropins and gonadal steroids, and the response to GnRH exceeds that seen in prepubertal children.

Treatment.

Constitutional delayed puberty should be ruled out before a diagnosis of isolated deficiency of GnRH is established and treatment is initiated. Testicular volume of less than 4?mL by 14 yr of age occurs in about 3% of boys, but true hypogonadotropic hypogonadism is a rare condition. Even relatively moderate delays in sexual development and growth may result in significant psychologic distress and require attention. Initially, an explanation of the variations characteristic of puberty and reassurance suffice for the majority of boys. If by 15 yr of age there is no clinical evidence of puberty beginning, and the testosterone level is less than 50?ng/dL, a brief course of testosterone is indicated. Testosterone enanthate, 100?mg intramuscularly once monthly for 4–6 mo, usually results in an increase in the signs of secondary sexual characteristics and an increase in growth velocity; it may initiate puberty and may differentiate constitutional delay in puberty from isolated gonadotropin deficiency. The age of initiation of this treatment must be individualized.

Patients with established deficiency of gonadotropins should be treated with the same program of repository testosterone as that used for those with primary testicular deficiency (see Chapter 577.1). With this therapy, the testes will remain small. Treatment with hCG, given subcutaneously or intramuscularly in doses of 500–1,000?IU, three times weekly, stimulates growth of the testes and spermatogenesis. If, after 6–12 mo of therapy, sufficient growth of the testes has not occurred, human menopausal gonadotropin may be added in doses of 37.5–150?IU, three times weekly. It may require up to 2 yr of treatment to achieve adequate spermatogenesis in adults. Recombinantly produced gonadotropins are able to stimulate gonadal growth and function.

A more physiologic, but cumbersome, form of treatment consists of episodic administration (subcutaneously or intravenously) of GnRH. Long-term therapy has been provided with a programmable peristaltic infusion pump. Most patients require about 2 yr of treatment to maximize testicular growth and achieve spermatogenesis.

Chapter 578 - Pseudoprecocity Resulting from Tumors of the Testes

Leydig cell tumors of the testes are rare causes of precocious pseudopuberty and cause asymmetric enlargement of the testes. They account for 3% of all testicular tumors. Leydig cells are sparse before puberty; tumors derived from them are more common in the adult. The reported cases in children include one member in each of two pairs of identical twins. These tumors are usually unilateral and benign; 10% may become malignant. Reinke crystalloids are a characteristic microscopic feature but occur in fewer than 50% of Leydig cell tumors. A gsp mutation was described in one testicular Leydig cell tumor. In adult testes, testicular germ cell tumors, but not Sertoli cell tumors or Leydig cell tumors, exhibit biallelic expression of the human *H19* gene.

The *clinical manifestations* are those of puberty in the male; onset occurs usually from 5–9 yr of age. Gynecomastia has been described. The tumor of the testis can usually be readily felt; the contralateral unaffected testis is normal in size for the age of the patient.

Plasma levels of testosterone are markedly elevated. Follicle-stimulating hormone and luteinizing hormone levels are suppressed, and there is no response to gonadotropin-releasing hormone. Ultrasonography may aid in the detection of small nonpalpable tumors. Fine-needle aspiration biopsy may help define the diagnosis.

Treatment consists of surgical removal of the affected testis. Progression of virilization ceases, and partial reversal of the signs of precocity may occur.

Testicular adrenal rests may develop into tumors that mimic Leydig cell tumors; in the absence of Reinke crystals, these two tumors cannot be differentiated histologically. Adrenal rest tumors are usually bilateral and occur in children with congenital adrenal hyperplasia, usually salt-losing patients, during adolescence or young adult life. The stimulus for the growth of the adrenal rests is inadequate corticosteroid suppressive therapy, and treatment with adequate doses almost always results in their regression. Definite evidence of the origin of these tumors has been achieved by demonstrating their 21-hydroxylase activity. The misdiagnosis of these tumors in patients with congenital adrenal hyperplasia has led to unnecessary orchidectomy.

Fragile X syndrome is the most frequent cause of hereditary mental retardation, with an incidence of 1/2,000 births. It is caused by the amplification of a polymorphic CGG repeat in the 5' untranslated region of the *FMRI* gene at Xp17.3. Amplified beyond 200 units, the repeat CGG sequence leads to methylation of the promoter region of FMRI and to a lack of gene product (FMRP). A cardinal characteristic of the condition is testicular enlargement (macro-orchidism), reaching 40–50?mL after puberty. Although the condition has been recognized in a child as young as 5 mo of age, affected boys younger than 6 yr of age rarely have testicular enlargement; by 8–10 yr of age, most have testicular volumes greater than 3?mL. The testes are enlarged bilaterally, are not nodular, and are histologically normal. Results of hormonal studies are normal. Direct DNA analysis searching for CGG repeat sequences permits definitive diagnosis (see Chapter 70).

Sex cord tumors with annular tubules of the testes can cause breast development in young boys. These tumors usually are associated with Peutz-Jeghers syndrome; they occur bilaterally, are multifocal, and are detectible by ultrasonography. Excessive production of aromatase ($P450_{arom}$) causes feminization of these boys.

In boys with *unilateral cryptorchidism*, the contralateral testis is about 25% larger than normal for age. Testicular enlargement has also been noted in boys with Henoch-Schönlein purpura and lymphangiectasia. Epidermoid and dermoid cysts of the testes have been reported rarely.

Chapter 579 - Gynecomastia

Gynecomastia, the occurrence of mammary tissue in the male, is a common condition. True gynecomastia (the presence of granular breast tissue) needs to be distinguished from pseudogynecomastia (consisting of only adipose tissue) seen in overweight boys. Gynecomastia is usually a sign of estrogen-androgen imbalance; its cause is often obscure. It occurs in most newborn males as a result of stimulation by maternal hormones; the effect disappears in a few weeks.

During early to mid puberty, approximately two thirds of boys develop various degrees of subareolar hyperplasia of the breasts. *Physiologic pubertal gynecomastia* may involve only one breast, and it is not unusual for both breasts to enlarge at disproportionate rates or at different times. Tenderness of the breast is common but transitory. Spontaneous regression may occur within a few months; it rarely persists longer than 2 yr. Mean concentrations of follicle-stimulating hormone, luteinizing hormone, prolactin, testosterone, estrone, and estradiol are the same as in boys without gynecomastia. When levels are correlated with stage of puberty, a decreased ratio of testosterone to estradiol is found in boys with gynecomastia. Cultured pubic skin fibroblasts from boys with gynecomastia show excessive aromatase activity. *Treatment* usually consists of reassuring the boy and his family of the physiologic and transient nature of the phenomenon. When the enlargement is striking and persistent and causes serious emotional disturbance to the patient, treatment may be justified. Medical treatment is generally aimed at

decreasing the estrogen/androgen ratio. Danazol has antiestrogenic effects but also numerous untoward side effects. Aromatase inhibitors such as testolactone and anastrozole are being evaluated for use in patients with gynecomastia. Surgical removal of the enlarged breast tissue is rarely indicated. One technique involves endoscopically assisted transaxillary removal of glandular tissue.

Benign, self-limited, and usually transient gynecomastia has been reported in prepubertal children during the initiation of therapy with human growth hormone.

Occasionally, breast development may mimic female breast development (to Tanner stages 3–5) and fails to regress. *Familial gynecomastia* has occurred in several kindreds as an X-linked or autosomal dominant sex-limited trait. Levels of gonadotropins, testosterone, prolactin, and steroid-binding globulins are normal. Increased peripheral conversion of C19-steroids to estrogens (increased aromatization) has been found in familial and sporadic cases of gynecomastia and

may explain some instances of this condition.

A report of the *syndrome of aromatase excess* in a father and his son and daughter suggests autosomal dominant inheritance. There was gynecomastia in the 9-yr-old boy and macromastia and isosexual precocity in his 7.5-yr-old sister. Excess aromatase activity was shown in skin fibroblasts and transformed lymphocytes in vitro. This was associated with $P450_{arom}$ polymorphism that suggested a sequence change in the $P450_{arom}$ promoter region. In mice, disruption of the *dax1* gene causes increased aromatase expression.

In prepubertal children with gynecomastia, an *exogenous source of estrogens* must be sought. Accidental or therapeutic exposure to small amounts of exogenous estrogens by inhalation, percutaneous absorption, or ingestion may cause gynecomastia. Three boys developed gynecomastia after indirect exposure to their mothers' custom-compounded topical estrogen-containing creams. Increased pigmentation of the nipple and areola should suggest this cause. Exposure to medications that decrease levels of androgens, especially free androgens, increase estradiol, or displace androgens from breast androgen receptors may result in gynecomastia.

Several other pathologic conditions may cause gynecomastia. It has been observed in children with congenital virilizing adrenal hyperplasia (e.g., 11ß-hydroxylase deficiency). It may be associated with Leydig cell tumors of the testis or with feminizing tumors of the adrenal gland. Several boys with the *Peutz-Jeghers syndrome* and gynecomastia had *sex-cord tumors with annular tubules* of the testes. The testes may not be enlarged; the tumor is usually multifocal and bilateral. Excessive aromatase production accounts for the gynecomastia. This condition occurs in patients with Klinefelter syndrome and with other types of testicular failure (hypergonadotropic states). It is a common finding in boys with certain types of male pseudohermaphroditism (particularly Reifenstein syndrome), with the androgen insensitivity syndromes, and with the 17-ketosteroid reductase defect. When gynecomastia is associated with galactorrhea, a prolactinoma should be considered. In a pubertal boy with fibrolamellar carcinoma of the liver, the associated gynecomastia and elevated estrogen level were attributed to increased aromatization of circulating androgens by the tumor. In an 8-yr-old boy with a calcifying Sertoli cell tumor, the gynecomastia was postulated to be the result of peripheral aromatization of androgens derived from Leydig cells newly differentiated from interstitial cells stimulated by the tumor. Hyperthyroidism alters the androgen:estrogen ratio by increasing bound androgen and decreasing the free testosterone and may result in gynecomastia.

In adults, gynecomastia occurs with liver cirrhosis, with digitalis therapy for congestive heart failure, bronchogenic carcinoma, administration of various nonsteroidal therapeutic agents, and heavy marijuana smoking. Ketoconazole, an antifungal drug, causes gynecomastia by directly inhibiting testosterone synthesis. Spironolactone, methyldopa, phenothiazines, antidepressants, coumadin, digitalis, and heroin have all been associated with gynecomastia.

Chapter 580 - Hypofunction of the Ovaries

Hypofunction of the ovaries may be caused by congenital failure of development, postnatal destruction (primary or hypergonadotropic hypogonadism), or lack of stimulation by the pituitary and or hypothalamus (secondary or tertiary hypogonadotropic hypogonadism). Many chronic diseases may result in hypogonadotropic hypogonadism.

580.1 Hypergonadotropic Hypogonadism in the Female (Primary Hypogonadism)

Diagnosis of hypergonadotropic hypogonadism before puberty is difficult. Except in the case of Turner syndrome, most affected patients have no prepubertal clinical manifestations.

TURNER SYNDROME

Turner described a syndrome consisting of sexual infantilism, webbed neck, and cubitus valgus in adult females (also see Chapter 70). Ullrich described an 8-yr-old girl with short stature and many of the same phenotypic features. The term *Ullrich-Turner syndrome* is frequently used in Europe but rarely used in the United States. The condition is defined as the combination of the characteristic phenotypic features accompanied by complete or partial absence of the second X chromosome with or without mosaicism.

Pathogenesis.

Half the patients with Turner syndrome have a 45,X chromosomal complement. About 15% of patients are mosaics for 45,X and a normal cell line (45,X/46,XX). Other mosaics with isochromosomes, 45,X/46,X,i(Xq); with rings, 45,X/46,X,r(X); or with fragments, 45,X/46fra, occur less often. The single X is of maternal origin in 50–70% of 45,X patients. The mechanism of chromosome loss is unknown, and the risk for the syndrome does not increase with maternal age. The genes involved in the Turner phenotype are X-linked genes that escape inactivation. A major locus involved in the control of linear growth has been mapped within the pseudoautosomal region of the X chromosome (PAR 1). *SHOX,* a homeobox-containing gene of 170?kb of DNA within the PAR 1, is thought to be important for controlling growth in children with Turner

syndrome, in patients having idiopathic short stature, and in the Leri-Weill syndrome. Genes for the control of normal ovarian function are postulated to be on Xp and perhaps two “supergenes” on Xq.

Turner syndrome occurs in about 1/1,500–2,500 liveborn females. The frequency of the 45,X karyotype at conception is about 3.0%, but 99% of these are spontaneously aborted, accounting for 5–10% of all abortuses. Mosaicism (45,X/46,XX) occurs in a proportion higher than that seen with any other aneuploid state, but the mosaic Turner constitution is rare among the abortuses; these findings indicate preferential survival for mosaic forms.

The normal fetal ovary contains about 7 million oocytes, but these begin to disappear rapidly after the 5th mo of gestation. At birth, there are only 2 million (1 million active follicles); by menarche, there are 400,000–500,000; and at menopause, 10,000 remain. In the absence of one X chromosome, this process is accelerated, and nearly all oocytes are gone by 2 yr of age. In aborted 45,X fetuses, the number of primordial germ cells in the gonadal ridge appears to be normal, suggesting that the normal process is accelerated in patients with Turner syndrome. Eventually, the ovaries are described as “streaks” and consist only of connective tissue, but a few germ cells may persist.

Clinical Manifestations.

Many patients with Turner syndrome are recognizable at birth because of a characteristic edema of the dorsa of the hands and feet and loose skinfolds at the nape of the neck. Low birthweight and decreased length are common. Clinical manifestations in childhood include webbing of the neck, a low posterior hairline, small mandible, prominent ears, epicanthal folds, high arched palate, a broad chest presenting the illusion of widely spaced nipples, cubitus valgus, and hyperconvex fingernails. The diagnosis is often first suspected at puberty when sexual maturation fails to occur.

Short stature, the cardinal finding in all girls with Turner syndrome, may be present with minimal other clinical manifestations. The growth deceleration begins in infancy and young childhood, gets progressively more pronounced in later childhood and adolescence, and results in significant adult short stature. Sexual maturation fails to occur at the expected age. The mean adult height is 143–144?cm in the United States and most of northern Europe, but 140?cm in Argentina and 147?cm in Scandinavia (Fig. 580–1). The height is well correlated with the midparental height (average of the parents' heights). Specific growth curves have been developed for girls with Turner syndrome.

Associated defects are common. Complete cardiologic evaluation, including echocardiography, reveals isolated nonstenotic bicuspid aortic valves in one third to one half of patients. In later life, bicuspid aortic valve disease can progress to dilatation of the aortic root. Less frequent defects include aortic coarctation (20%), aortic stenosis, mitral valve prolapse, and anomalous pulmonary venous drainage. In a study of 170/393 females with Turner syndrome in Denmark, 38% of patients with

45,X chromosomes had cardiovascular malformations compared with 11% of those with mosaic monosomy X; the most common were aortic valve abnormalities and aortic coarctation. Webbed neck in patients with or without recognized syndromes is associated with both flow- and non–flow-related heart defects. Among patients with Turner syndrome, those with webbed neck have a much greater chance of having coarctation of the aorta than do those without webbed necks. Repeat cardiac evaluation should be considered even in those without prior findings of cardiac abnormalities during adolescence, and certainly before pregnancy is contemplated. Blood pressure should be routinely monitored even in the absence of cardiac or renal lesions and especially in those with suggestions of aortic root dilatation.

Figure 580.1-1 Turner syndrome in a 15-yr-old girl exhibiting failure of sexual maturation, short stature, cubitus valgus, and a goiter. There is no webbing of the neck. Karyotyping revealed 45,X/46,XX chromosome complement, and the urinary gonadotropin level was over 96 mouse units/24?hr; T_4 was 2.2?µg/dL.

One fourth to one third of patients have renal malformations on ultrasonographic examination (50% of those with 45,X karyotypes). The more serious defects include pelvic kidney, horseshoe kidney, double collecting system, complete absence of one kidney, and ureteropelvic junction obstruction. Idiopathic hypertension is also common. When the ovaries were examined by ultrasonography, older studies found a significant decrease in percentage of detectable ovaries from infancy to later childhood. A subsequent report found no such age-related differences in a cross sectional (N = 142) and longitudinal study (N = 38) conducted in Italy; 27–46% of patients had detectable ovaries at various ages; 76% of those with X mosaicism and 26% of those with 45,X karyotypes had detectable ovaries.

Sexual maturation usually fails to occur, but 10–20% of girls have spontaneous breast development, and a small percentage may have menstrual periods. Pregnancies have been reported for spontaneously menstruating patients with Turner syndrome. Premature menopause, increased risk of miscarriage, and offspring with increased risk of trisomy 21 have been reported in some of these women. A woman with a 45, X/46, X, r(X) karyotype treated with hormone replacement therapy had three pregnancies, resulting in a normal 46,XY male infant, a spontaneous abortion, and a healthy term female with Turner syndrome 45X/46Xr(X).

Antithyroid antibodies, thyroid peroxidase, or thyroglobulin antibodies occur in 30–50% of patients. The prevalence increases with advancing age. Ten to 30% have autoimmune thyroid disease, with or without the presence of a goiter. Age-dependent abnormalities in carbohydrate metabolism characterized by abnormal glucose tolerance and insulin resistance and, only rarely, frank type 2 diabetes occur in patients with

Turner syndrome. Cholesterol levels are elevated in adolescence, regardless of body mass index or karyotype.

Inflammatory bowel disease, both Crohn disease and ulcerative colitis; gastrointestinal bleeding due to abnormal mesenteric vasculature; and delayed gastric emptying time have all been reported.

Sternal malformations can be detected by lateral chest radiography. An increased carrying angle at the elbow is usually not clinically significant. Scoliosis occurs in about 10% of adolescent girls. Reported eye findings include anterior segment dysgenesis and keratoconus. Pigmented nevi become more prominent with age; melanocytic nevi are common. Essential hyperhidrosis, torus mandibularis, and alopecia areata occur rarely.

Recurrent bilateral otitis media develops in about 75% of patients. Sensorineural hearing deficits are common, and the frequency increases with age. Problems with gross and fine motor-sensory integration, failure to walk before 15 mo of age, and early language dysfunction often raise questions about developmental delay, but intelligence is normal in most patients. However, mental retardation does occur in patients with 45,X/46,X,r(X); the ring chromosome is unable to undergo inactivation and leads to two functional X chromosomes. In adults, deficits in perceptual spatial skills are more common than they are in the general population. Evidence suggests the existence of an imprinted X-linked locus that affects cognitive function. Patients with Turner syndrome with a 45,X karyotype whose X chromosome was of paternal origin were significantly better adjusted and had superior verbal and higher-order executive function skills then did those whose X chromosome was of maternal origin.

The prevalence of mosaicism depends in large part on the techniques used for studying chromosomal patterns. The use of fluorescent in situ hybridization and reverse transcription-polymerase chain reaction (PCR) has increased the reported prevalence of mosaic patterns to as high as 60–74%.

Mosaicism involving the Y chromosome occurs in 5%. A population study of 114 Danish women (mean age 27 ± 13 yr) using PCR with five different primer sets found Y chromosome material in 12.2%. Gonadoblastoma among Y-positive patients occurred in 7–10%. Therefore, the current recommendation that prophylactic gonadectomy should be performed even in the absence of MRI or CT evidence of tumors may need to be re-evaluated in the future. The gonadoblastoma locus on the Y chromosome (GBY) maps close to the Y centromere. The presence of only the *SRY* (sex determining region on Y) locus is not sufficient to confer increased susceptibility for the development of gonadoblastoma. A careful study of 53 patients with Turner syndrome by nested PCR excluded low-level Y mosaicism in almost all cases. A second round of PCR detected *SRY* on the distal short arm of the Y chromosome in only two subjects. Therefore, routine PCR for Y chromosome detection for the purpose of assigning gonadoblastoma risk does not seem indicated.

In patients with 45,X/46,XX mosaicism, the abnormalities are attenuated and fewer; short stature is as frequent as it is in the 45,X patient and may be the only manifestation of the condition other than ovarian failure (see Fig. 580–1).

Laboratory Findings.

Chromosomal analysis must be considered in all short girls. In a systematic search,

using Southern blot analysis of leukocyte DNA, Turner syndrome was detected in 4.8% of girls referred to an endocrinology service because of short stature. Girls referred with already recognized Turner phenotypes were excluded from analysis. Patients with a marker chromosome in some or all cells should be tested for DNA sequences at or near the centromere of the Y chromosome.

Ultrasonography of the heart, kidneys, and ovaries is indicated after the diagnosis is established. The most common skeletal abnormalities are shortening of the 4th metatarsal and metacarpal bones, epiphyseal dysgenesis in the joints of the knees and elbows, Madelung deformity, scoliosis, and, in older patients, inadequate osseous mineralization.

Plasma levels of gonadotropins, particularly follicle-stimulating hormone (FSH), are markedly elevated to greater than those of age-matched controls during infancy; at 2–3 yr of age, a progressive decrease in levels occurs until they reach a nadir at 6–8 yr of age, and by 10–11 yr, they rise to adult castrate levels.

Thyroid antiperoxidase antibodies should be checked periodically and, if positive, levels of thyroxine and thyroid-stimulating hormone should be obtained. Extensive studies have failed to establish that growth hormone deficiency plays a primary role in the pathogenesis of the growth disorder. Defects in normal secretory patterns of growth hormone are seen in adolescents but not younger girls with Turner syndrome. In vitro, monocytes and lymphocytes show decreased sensitivity to insulin-like growth factor-1 (IGF-1).

The American Academy of Pediatrics has published a comprehensive guide to the health supervision of children with Turner syndrome.

Treatment.

Treatment with recombinant human growth hormone increases height velocity and ultimate stature in most but not all children. Many girls achieve heights of greater than 150?cm with early initiation of treatment. By adjusting growth hormone doses according to growth velocity measures, 80% of 14 patients achieved final adult height better than 2?SD less than the mean for the general population (mean height 155?cm). In a large multicenter placebo-controlled U.S. clinical trial, 99 patients with Turner syndrome who started receiving growth hormone at a mean age of 10.9 yr at doses between 0.27 and 0.36?mg/kg/wk achieved a mean height of 149?cm, with nearly one third reaching heights greater than 152.4?cm (60?in). In the Netherlands, higher doses of growth hormone (up to 0.63?mg/kg/wk in the 3rd yr of treatment) resulted in 85% of the subjects reaching adult heights in the normal range for the Dutch reference population. Growth hormone treatment should be initiated in early childhood and/or when there is evidence of growth velocity attenuation on specific Turner syndrome growth curves. The starting dose of growth hormone is 0.375?mg/kg/wk. Growth hormone therapy does not significantly aggravate carbohydrate tolerance and does not result in marked adverse events in patients with Turner syndrome. Serum levels of IGF-1 should be routinely monitored during growth hormone treatment.

Replacement therapy with estrogens is indicated, but there is little consensus about the optimal age at which to initiate treatment. The psychologic preparedness of the patient to accept therapy must be taken into account. The improved growth achieved by girls treated with growth hormone in childhood permits initiation of estrogen replacement at 12–13 yr. For greater gains in height, especially for those in whom growth hormone treatment is not initiated until later in childhood or adolescence, estrogen treatment may need to be delayed until 14–15 yr of age. Careful consideration should be given to the sometimes conflicting psychologic consequences of delaying estrogen therapy for the purpose of achieving better ultimate height. The effects on bone accretion should also be considered. The availability of very low dose estrogen replacement therapy in the future may obviate the need to choose between appropriate pubertal replacement and optimizing height potential. Estrogen therapy improves verbal and nonverbal memory in girls with Turner syndrome.

Premarin, a conjugated estrogen, 0.3–0.625?mg, or Estrace, 0.5?mg (micronized estradiol), given daily for 3–6 mo is usually effective in inducing puberty. The estrogen then is cycled (taken on days 1–23), and Provera, a progestin, is added (taken on days 10–23) in a dose of 5–10?mg daily. In the remainder of the calendar month, during which no treatment is given, withdrawal bleeding usually occurs.

Prenatal chromosome analysis for advanced maternal age has revealed a frequency of 45,X/46,XX that is 10 times higher than when diagnosed postnatally. Most of these patients have no clinical manifestations of Turner syndrome, and levels of gonadotropins are normal. Awareness of this mild phenotype is important in counseling patients.

Psychosocial support for these girls is an integral component of treatment. The Turner Syndrome Society, which has local chapters in the United States, and similar groups in Canada and other countries provide a valuable support system for these patients and their families in addition to that given by the health care team.

Successful pregnancies have been carried to term using ovum donation and in vitro fertilization.

In adult women with Turner syndrome, there seems to be a high prevalence of undiagnosed bone mineral density, lipid, and thyroid abnormalities. Glucose intolerance, diminished first-phase insulin response, elevated blood pressure, and lowered fat free mass are common. Glucose tolerance worsens, but fat free mass and blood pressure and general physical fitness improve with sex hormone replacement.

In an analysis of a cohort of 597 women with cytogenetically proven Turner syndrome in Denmark (Danish Cytogenetic Register), neoplasms were identified in 20 women. Only one case, a Wilms tumor, was diagnosed in childhood. Colon cancer was observed in five patients for a relative risk of 6.9. No case of dysgerminoma or gonadoblastoma was found even in the 20 women with Y chromosomes.

Careful and appropriate health maintenance should be continued for patients with

Turner syndrome throughout their lives.

XX GONADAL DYSGENESIS

Some phenotypically and genetically normal females have gonadal lesions identical to those in 45,X patients but without somatic features of Turner syndrome; their condition is termed *pure gonadal dysgenesis* or *pure ovarian dysgenesis*. Here we discuss only those with the XX chromosome constitution. XY gonadal dysgenesis, also termed *Swyer syndrome*, is discussed later in the section on male pseudohermaphroditism. These two conditions are distinct entities; XX and XY gonadal dysgenesis have not been reported in the same family.

The disorder is rarely recognized in children because the external genitals are normal, no other abnormalities are visible, and growth is normal. At pubertal age, sexual maturation fails to take place. Plasma gonadotropin levels are elevated. Delay of epiphyseal fusion results in a eunuchoid habitus. Pelvic ultrasonography reveals streak ovaries.

Affected siblings, parental consanguinity, and failure to uncover mosaicism all point to female-limited autosomal recessive inheritance. The disorder appears to be especially frequent in Finland (1/8,300 liveborn girls). In this population, several mutations in the FSH receptor gene (on chromosome 2p) were demonstrated as the cause of the condition. FSH receptor gene mutations were not detected in Mexican women with 46,XX gonadal dysgenesis. In some patients, XX gonadal dysgenesis has been associated with sensorineural deafness *(Perrault syndrome)*. A patient with this condition and concomitant growth hormone deficiency and virilization has also been reported. There may be distinct genetic forms of this disorder. Müllerian agenesis, or the Mayer-Rokitansky-Küster-Hauser syndrome, second to gonadal dysgenesis as the most common cause of primary amenorrhea occurring in 1:4,000–1:5,000 females, has been reported in association with 46,XX gonadal dysgenesis in a 17-yr-old adolescent with primary amenorrhea and lack of breast development. One case of dysgerminoma with syncytiotrophoblastic giant cells was reported. Treatment consists of estrogen replacement therapy.

45,X/46,XY GONADAL DYSGENESIS

45,X/46,XY gonadal dysgenesis, also called *mixed gonadal dysgenesis*, has extreme phenotypic variability postnatally that may extend from a Turner-like syndrome to a male phenotype with a penile urethra; it is possible to delineate three major clinical phenotypes. Short stature is a major finding in all affected children. Ninety per cent of prenatally diagnosed cases have a normal male phenotype.

Some patients have no evidence of virilization; they have a female phenotype and often have the somatic signs of Turner syndrome. The condition is discovered prepubertally when chromosomal studies are made in short girls, or later when chromosomal studies are made because of failure of sexual maturation. Fallopian tubes and the uterus are present. The gonads consist of intra-abdominal undifferentiated streaks; chromosome study of the streak often reveals an XY cell line. The streak gonad differs somewhat from that in girls with Turner syndrome; in addition to wavy connective tissue, there are often tubular or cordlike structures, occasional clumps of granulosa cells, and, frequently, mesonephric or hilar cells.

Some children have mild virilization manifested only by prepubertal clitorimegaly. Normal müllerian structures are present, but at puberty virilization occurs. These patients usually have an intra-abdominal testis, a contralateral streak gonad, and bilateral fallopian tubes.

Most children present with frank ambiguity of the genitals in infancy. A testis and vas deferens are found on one side in the labioscrotal fold, and a streak gonad is identified on the contralateral side. Despite the presence of a testis, fallopian tubes are often present bilaterally. An infantile or rudimentary uterus is almost always present.

Other genotypes and phenotypes have been described. About 25% of 200 analyzed patients have a dicentric Y chromosome (45,X/46,X,dic Y). In some patients, the Y chromosome may be represented by only a fragment (45,X/45,X +fra); application of Y-specific probes can establish the origin of the fragment. It is not clear why the same genotype (45,X/46,XY) can result in such diverse phenotypes.

Children with a female phenotype present no problem in gender of rearing. Patients who are only slightly virilized are usually assigned a female gender of rearing before a diagnosis is established. Patients with ambiguity of the genitals are readily confused with various types of male pseudohermaphrodism. In most but not all instances, these children are best reared as females; the short stature, the ease of genital reconstruction, and the predisposition of the gonad to the development of malignancy favor this choice. In some patients followed to adulthood, the putative normal testis proves to be dysgenetic with eventual loss of Leydig and Sertoli cell function (see also Chapter 577). In an analysis of 22 Australian patients with mixed gonadal dysgenesis, no significant associations or correlations were found between internal and external phenotypes or endocrine function and gonadal morphologic features. The sex of rearing was determined by the appearance of the external genitals. In 11 patients, basal and human chorionic gonadotropin–stimulated testosterone levels were lower than in control subjects.

Gonadal tumors, usually gonadoblastomas, occur in about 25% of these children. A gonadoblastoma locus has been localized to a region near the centromere of the Y chromosome (GBY). These germ cell tumors are preceded by the changes of carcinoma in situ. Accordingly, both gonads should be removed in all patients reared as girls, and the undifferentiated gonad should be removed in the patients reared as boys.

There is no correlation between the proportion of 45,X/46,XY cell lives in either blood or fibroblasts and phenotype. In the past, all patients came to clinical attention because of their abnormal phenotypes. However, 45,X/46,XY mosaicism is

found in about 7% of fetuses with true chromosome mosaicism encountered prenatally. Of 76 infants with 45,X/46,XY mosaicism diagnosed prenatally, 72 had a normal male phenotype, 1 had a female phenotype, and only 3 males had

hypospadias. Of 12 males whose gonads were examined, only 3 were abnormal. These data must be taken into account when counseling a family in which a 45,X/46,XY infant is discovered prenatally.

XXX, XXXX, AND XXXXX FEMALES

XXX Females.

Trisomy (autosome or sex chromosome) is the most common chromosomal abnormality in humans occurring in 4% of recognized pregnancies. The 47,XXX chromosomal constitution is the most frequent X chromosome abnormality in females, occurring in almost 1/1,000 liveborn females. In 68%, this condition is caused by maternal meiotic nondisjunction, but most 45,X and half of 47,XXY constitutions are caused by paternal sex chromosome errors. The phenotype is that of a normal female; affected infants and children are not recognized.

Sexual development and menarche are normal. Most pregnancies have resulted in normal infants. By 2 yr of age, delays in speech and language become evident and lack of coordination, poor academic performance, and immature behavior are seen. These girls tend to be tall and gangly, manifest behavior disorders, and are placed in special education classes. Using high-resolution MRI, 10 47,XXX subjects had lower amygdala volumes than 20 euploid controls; ten 47,XXY subjects had even lower amygdala volumes. There is marked variability within the syndrome, and a small proportion of affected girls are well coordinated, socially outgoing, and academically superior.

XXXX and XXXXX Females.

The great majority of females with these rare karyotypes have been mentally retarded. Commonly associated defects are epicanthal folds, hypertelorism, clinodactyly, transverse palmar creases, radioulnar synostosis, and congenital heart disease. Sexual maturation is often incomplete and may not occur at all. Nevertheless, three women with the tetra-X syndrome gave birth, but no pregnancies were reported in 49,XXXXX women. Most 48,XXXX women tend to be tall, with an average height of 169?cm, whereas short stature is a common feature of the 49,XXXXX phenotype.

NOONAN SYNDROME

Girls with Noonan syndrome show certain anomalies that also occur in girls with 45,X Turner syndrome, but they have normal 46,XX chromosomes. The most common abnormalities are the same as those described for males with Noonan syndrome (see Chapter 577.1). The phenotype differs from Turner syndrome in several respects. Mental retardation is often present, the cardiac defect is most often pulmonary valvular stenosis or an atrial septal defect rather than an aortic defect, normal sexual maturation usually occurs but is delayed 2 yr on average, and premature ovarian failure has been reported.

OTHER OVARIAN DEFECTS

Some young women with no chromosomal abnormality are found to have streak gonads that may contain only occasional or no germ cells. Gonadotropins are increased. *Cytotoxic drugs,* especially alkylating agents such as cyclophosphamide and busulfan, procarbazine, etoposide, and exposure of the ovaries to radiation for the treatment of malignancy are increasingly frequent causes of ovarian failure. Young women with Hodgkin disease demonstrate that combination chemotherapy and pelvic irradiation may be more deleterious than either therapy alone. Teenagers are more likely than older women to retain or recover ovarian function after irradiation or combined chemotherapy; normal pregnancies have occurred after such treatment. Current treatment regimens may result in some ovarian damage in most girls treated for cancer. The LD_{50} for the human oocyte has been estimated to be about 4?Gy; doses as low as 6?Gy have produced primary amenorrhea. Ovarian transposition before abdominal and pelvic irradiation in childhood can preserve ovarian function by decreasing the ovarian exposure to less then 4–7?Gy.

Autoimmune ovarian failure occurs in 60% of children older than 13 yr of age with *type I autoimmune polyendocrinopathy* (Addison disease, hypoparathyroidism, candidiasis). This condition, also known as polyglandular autoimmune disease (PGAD) type 1 is rare worldwide but not in Finland, where, as a result of a founder gene effect, it occurs in 1:25,000 people. The gene for this disorder is located on chromosome 21 and is associated with HLA-DR5. In patients with PGAD-1 and ovarian failure an association with HLA-A3 has been described. Affected girls may not develop sexually, or secondary amenorrhea may occur in young women. The ovaries may have lymphocytic infiltration or appear simply as streaks. Most affected patients have circulating steroid cell antibodies and autoantibodies to 21-hydroxylase.

The condition also occurs in young women as an isolated event or in association with other autoimmune disorders, leading to secondary amenorrhea *(premature ovarian failure [POF]).* It occurs in 0.2–0.9% of women younger than 40 years of age. Premature ovarian failure is a heterogeneous disorder with many causes: chromosomal, genetic, enzymatic, infectious, or iatrogenic. When associated with autoimmune adrenal disease, steroid cell autoantibodies are always present. These antibodies react with P450scc, 17a-OH, or 21-OH enzymes. When associated with an entire host of endocrine and nonendocrine autoimmune diseases and not adrenal autoimmunity, steroid cell autoantibodies are rarely found. A second autoimmune disorder, often subclinical, is found in 10–39% of adult patients with POF. One 17 yr old with idiopathic thrombocytopenic purpura and 47,XXX chromosomes had autoimmune POF.

Galactosemia, particularly the classic form of the disease, usually results in ovarian damage, beginning during intrauterine life. Levels of FSH and luteinizing hormone (LH) are elevated early in life. Ovarian damage may be due to deficient uridine diphosphate-galactose (see Chapter 76.2). The Denys-Drash syndrome, caused by a *WT1* mutation, can result in ovarian dysgenesis.

Ataxia-telangiectasia may be associated with ovarian hypoplasia and elevated gonadotropins; the cause is unknown. Gonadoblastomas and dysgerminomas have occurred in a few girls.

Hypergonadotrophic hypogonadism has been postulated to also occur because of

the resistance of the ovary to both endogenous and exogenous gonadotropins (Savage syndrome). This condition occurs also in women with POF. Antiovarian antibodies or FSH receptor abnormalities may cause this condition. Mutation of the FSH receptor gene has been reported as an autosomal recessive condition (see under XX Gonadal Dysgenesis). A few females with 46,XX chromosomes presenting in primary amenorrhea with elevated gonadotropin levels were found to have inactivating mutations of the LH receptor gene. This suggests that LH action is needed for normal follicular development and ovulation.

580.2 Hypogonadotropic Hypogonadism in the Female (Secondary Hypogonadism)

Hypofunction of the ovaries can result from failure to secrete normal levels of gonadotropins. The defect may lie in the anterior pituitary or, more commonly, in the hypothalamus.

Etiology

HYPOPITUITARISM (also see chapter 551).

Congenital or acquired lesions in or near the pituitary almost always result in impaired secretion of gonadotropins and other pituitary

hormones. In children with multiple pituitary hormone defects including gonadotropin deficiency, pituitary transcription factor defects such as in PROP-1 have been described. In children with idiopathic hypopituitarism, the defect is usually found in the hypothalamus. In these patients, administration of gonadotropin-releasing hormone (GnRH) results in increased plasma levels of FSH and LH, establishing the integrity of the pituitary gland.

ISOLATED DEFICIENCY OF GONADOTROPINS.

This heterogeneous group of disorders is sorted out with the help of the GnRH test. In most children, the pituitary is normal, with the defect residing in the hypothalamus.

Several sporadic instances of anosmia with hypogonadotropic hypogonadism have been reported. Anosmic hypogonadal females have also been reported in kindreds with Kallmann syndrome, but hypogonadism more frequently affects the males in these families. Mutations in the gene for the ß-subunit of FSH and LH have been reported.

Some autosomal recessive disorders such as the Laurence-Moon-Biedl, multiple lentigines, and Carpenter syndromes appear in some instances to include gonadotropic hormone deficiency. Girls with Prader-Willi syndrome may have hypogonadotropic hypogonadism. Girls with severe thalassemia may have gonadotropin deficiency from pituitary damage caused by chronic iron overload secondary to multiple transfusions. Anorexia nervosa frequently results in hypogonadotropic hypogonadism (see Chapter 104).

Diagnosis.

The diagnosis may be apparent in patients with other deficiencies of pituitary tropic hormones, but, as in males, it is difficult to differentiate isolated hypogonadotropic hypogonadism from physiologic delay of puberty. Repeated measurements of FSH and LH, particularly during sleep, may reveal the rising levels that herald the onset of puberty. Stimulation testing with GnRH or one of its analogues may help establish the diagnosis.

POLYCYSTIC OVARIES (STEIN-LEVENTHAL SYNDROME)

The classic polycystic ovaries syndrome (PCOS) is characterized by obesity, hirsutism, and secondary amenorrhea, with bilaterally enlarged polycystic ovaries, but these manifestations may not all be present (also see Chapter 544). Onset usually occurs at puberty or shortly thereafter; menstrual irregularities and hirsutism are the most frequent complaints. In the reproductive years, the condition is the most common cause of anovulatory infertility. Several terms have gained acceptance in describing these patients: *functional ovarian hyperandrogenism* and, especially in adults, *chronic hyperandrogenic anovulation.* There seems to be a strong relationship between premature adrenarche and the subsequent development of PCOS. The enlarged ovaries can often be felt on combined rectal and abdominal palpation and are always demonstrable by ultrasonography (see Chapter 544).

The cause of the disorder in most patients is unsettled despite intensive investigation. PCOS is a heterogeneous condition that may be associated with several distinct entities, such as 21-hydroxylase deficiency, deficiency of 3-hydroxysteroid dehydrogenase, and deficiency of ovarian 17-ketoreductase, the enzyme that converts androstenedione to testosterone and estrone to estradiol. Conversion of cholesterol to pregnenolone by the cholesterol side-chain cleavage enzyme P450scc, encoded by the gene *CYP11A,* occurs after cholesterol enters the mitochondria aided by the steroidogenic acute regulatory protein (StAR). DAX-1 can repress StAR gene expression, and SF-1 regulates SF-1. *CYP11A* or DAX-1 were found in hyperandrogenic hirsute women with and without menstrual disturbances. In most patients with PCOS, the elevated plasma level of free testosterone or androstenedione is not suppressed by dexamethasone, ruling out an adrenal cause of the disorder. In some patients, serum levels of total testosterone may not be elevated but serum levels of free testosterone are, and sex hormone-binding globulins are markedly diminished. About 75% of patients have an increased ratio of LH to FSH levels, an increased amplitude and frequency of plasma LH levels, and an exaggerated response to GnRH. Inhibin B levels are high at baseline and lack normal pulsatile changes. Premenarcheal girls may have an early morning rise in LH rather than the characteristic nocturnal one. The perturbances of LH secretion are believed to bring about hyperplasia of theca cells, arrested follicular development, and impaired estradiol production. Aberrant follicular development, one of the hallmarks of PCOS, may be related to dysregulation of oocyte growth differentiation factor-9 (GDF-9) but not bone morphogenic factor-15 (BMP-15), both known oocyte growth factors. These effects lead to hyperandrogenemia and irregular cycles or amenorrhea. In children having congenital virilizing syndromes, the hypothalamic-pituitary axis appears to be programmed for hypersecretion of LH at

puberty, leading to hyperandrogenism even when adrenal androgens are thought to be adequately suppressed. Several common polymorphisms in the interlukin-6 gene promoter are associated with hyperandrogenism.

There is an association between hyperandrogenism and insulin resistance. Especially in obese patients, PCOS may be associated with hyperinsulinism, insulin resistance, and acanthosis nigricans. Because of the high prevalence of PCOS, it needs to be counted among the most common conditions associated with glucose intolerance and type II diabetes. Adolescents with PCOS tend to have a higher incidence (7/27 in one study) of impaired glucose tolerance. The insulin resistance seems to be related to excessive serine phosphorylation of the insulin receptor. The same process, serine phosphorylation, is important in regulating the activity of P450c17, a major enzyme involved in androgen biosynthesis. Therefore, some have postulated this defect as the single abnormality that may be responsible for both the insulin resistance and hyperandrogenism seen in PCOS. Variations in the gene encoding the cysteine protease calpain-10 may be associated with increased susceptibility to type 2 diabetes. The 112/121 haplotype is associated with both insulin levels and a 2-fold risk of PCOS in white and African American women.

For *diagnosis* of PCOS, measurements of serum LH, FSH, prolactin, free testosterone, and sex hormone–binding globulin as well as dehydroepiandrosterone sulfate (DHEAS) are helpful. Brothers of women with PCOS have elevated DHEAS levels, whereas in sisters of women with PCOS markers of insulin resistance (elevated fasting insulin levels and decreased fasting glucose/insulin ratios) are associated with hyperandrogenemia but not menstrual irregularities. Measures of insulin resistance however, may have significant intraindividual variations in women with PCOS. Complex stimulation and inhibitory pharmacologic manipulation have been used to distinguish between adrenal and ovarian causes of hyperandrogenism. Basal and adrenocorticotropic hormone stimulated adrenal steroid levels may reveal subtle adrenal steroidogenic defects.

A deficiency of 17-ketoreductase is suggested when there are affected brothers or when the estrone:estradiol and androstenedione:testosterone ratios are increased. Women treated with valproate for epilepsy before 20 yr of age often have PCOS and elevated serum testosterone levels, but their levels of LH are normal.

The optimal method of *treatment* is still evolving. The mainstay of therapy is ovarian suppression with oral contraceptives containing nonandrogenic progestins such as desogestrel (Desogen). Spironolactone, in addition to oral contraceptives, has been the main pharmacologic agent available in the United States to diminish hirsutism. Further suppression can be achieved with testolactone, a compound with antiandrogen and weak progestin properties. Electrolysis and laser therapy are the main nonpharmacologic treatment modalities for hirsutism. Attention to

the obesity is important because its correction often leads to correction of the insulin resistance. Oral agents to treat type II diabetes are beginning to be used to improve insulin resistance in patients with PCOS. Insulin-sensitizing agents such as metformin and troglitazone decrease hyperinsulinemia and ovarian hyperandrogenism in women. Three months of metformin treatment improves insulin resistance and the exaggerated adrenal androgen responses to ACTH. d-*Chiro*-inositol treatment of women with PCOS improves insulin action, thus enhancing ovarian function while decreasing serum androgen levels. This approach stimulates postreceptor insulin action. Naltrexone, an opioid antagonist, decreases insulin secretion in hyperinsulinemic patients with PCOS.

Chapter 581 - Pseudoprecocity Due to Lesions of the Ovary

Ovarian tumors are rare in pediatrics, thought to occur at a rate of 2.6/100,000. Ovarian malignancies, the most common genital neoplasms in adolescence, account for 1% of childhood cancers. More then 60% are germ cell tumors, most of which are dysgerminomas that can secrete tumor markers and hormones

(see Chapter 495). Next most common are epithelial cell tumors (~20%), and nearly 10% are sex cord/stromal tumors (granulosa, Sertoli cell, and mesenchymal tumors). Multiple tumor markers can be seen in ovarian tumors, including a-fetoprotein, human chorionic gonadotropin (hCG), carcinoembryonic antigen, oncoproteins, p105, p53, *KRAS* mutations, cyclin D1, epidermal growth factor–related proteins and receptors, cathepsin B, and others. Various levels of inhibin-activin subunit gene expression were detected in ovarian tumors.

Functioning lesions of the ovary consist of benign cysts or malignant tumors. The majority synthesize estrogens; a few synthesize androgens.

Estrogenic Lesions of the Ovary.

These lesions cause isosexual precocious sexual development but account for only a small percentage of all cases of precocity. Benign ovarian follicular cysts are the most common tumors associated with isosexual precocious puberty in girls; they may rarely be gonadotropin dependent.

JUVENILE GRANULOSA CELL TUMOR.

In childhood, the most common neoplasm of the ovary with estrogenic manifestations is the granulosa cell tumor, although it composes 1–10% of all ovarian tumors. These tumors have distinctive histologic features that differ from those encountered in older women (adult granulosa cell tumor). The cells have high mitotic activity, follicles are often irregular, Call-Exner bodies are rare, and luteinization is frequent. The tumor may be solid or cystic, or both. They are usually benign. In a few instances, this tumor has been associated with multiple enchondromas *(Ollier disease)* and, in fewer still, with multiple subcutaneous

hemangiomas *(Maffucci syndrome)*.

CLINICAL MANIFESTATIONS AND DIAGNOSIS.

The tumor has been observed in newborns and may manifest with sexual precocity at 2 yr of age or younger; about half of these tumors have occurred before 10 yr of age. The mean age at diagnosis is 7.5 yr. The tumors are almost always unilateral. The breasts become enlarged, rounded, and firm and the nipples prominent. The external genitals resemble those of a normal girl at puberty, and the uterus is enlarged. A white vaginal discharge is followed by irregular or cyclic menstruation. Ovulation, however, does not occur. The presenting manifestation may be abdominal pain or swelling. Pubic hair is usually absent unless there is mild virilization.

A mass is readily palpable in the lower portion of the abdomen in most children by the time sexual precocity is evident. The tumor may be small, however, and escape detection even on careful rectal and abdominal examination; the tumors may be detected by ultrasonography, but multidetector CT scans are most sensitive. Most such tumors (90%) are diagnosed at very early stages of malignancy (FIGO, International Federation of Gynecology and Obstetrics, stage I).

Plasma estradiol levels are markedly elevated. Plasma levels of gonadotropins are suppressed and do not respond to gonadotropin-releasing hormone stimulation. Levels of müllerian-inhibiting substance (anti-müllerian hormone), inhibin, and a-fetoprotein may be elevated. Osseous development is moderately advanced.

TREATMENT AND PROGNOSIS.

The tumor should be removed as soon as the diagnosis is established. Prognosis is excellent because fewer than 5% of these tumors in children are malignant. Advanced stage tumors, however, behave very aggressively and require difficult decisions regarding surgical approaches as well the use of radiation and chemotherapy. In adults with granulosa cell tumors, *p53* expression is associated with unfavorable prognosis. Vaginal bleeding immediately after removal of the tumor is common. Signs of precocious puberty abate and may disappear within a few months after the operation. The secretion of estrogens returns to normal.

Sex cord tumor with annular tubules is a distinctive tumor, thought to arise from granulosa cells, that occurs primarily in patients with Peutz-Jeghers syndrome. These tumors are multifocal, bilateral, and usually benign. The presence of calcifications aids ultrasonographic detection. Increased aromatase production by these tumors results in gonadotropin-independent precocious puberty. Inhibin A and B levels are elevated and decrease after tumor removal. In one study, 9 of 13 sex cord/stromal tumors exhibited follicle-stimulating hormone receptor mutations, suggesting a role for such mutation in the development of these tumors.

Chorioepithelioma has been reported only rarely. This very malignant tumor is thought to arise from a pre-existing teratoma. The usually unilateral tumor produces large amounts of hCG, which stimulates the contralateral ovary to secrete estrogens and progesterone. Elevated levels of hCG are diagnostic.

FOLLICULAR CYST.

Small ovarian cysts (<0.7?cm in diameter) are common in prepubertal children. At puberty and in girls with true isosexual precocious puberty, larger cysts (1–6?cm) are often seen; these are secondary to stimulation by gonadotropins. However, similar larger cysts occur occasionally in young girls with precocious puberty in the absence of luteinizing hormone and follicle-stimulating hormone. Because surgical removal or spontaneous involution of these cysts results in regression of pubertal changes, there is little doubt that they are its cause. The mechanism of production of these autonomously functioning cysts is unknown. Such cysts may form only once, or they may disappear and recur, resulting in waxing and waning of the signs of precocious puberty. They may be unilateral or bilateral. The sexual precocity that occurs in young girls with McCune-Albright syndrome is usually associated with autonomous follicular cysts caused by a somatic-activating mutation of the G protein occurring early in development (see Chapter 556.6). Gonadotropins are suppressed, and estradiol levels are often markedly elevated, but they may fluctuate widely and even return to normal. Gonadotropin-releasing hormone stimulation fails to evoke an increase in gonadotropins. Because gonadotropins are suppressed in these children, the mechanism of ovarian stimulation is unknown. Ultrasonography is the method of choice for the detection and monitoring of such cysts. A short period of observation to ascertain a lack of spontaneous resolution is advisable before cyst aspiration or cystectomy is considered. Cystic neoplasms must be considered in the differential diagnosis.

Androgenic Lesions of the Ovary.

Virilizing ovarian tumors are rare at all ages but particularly so in prepubertal girls. The *arrhenoblastoma* has been reported as early as 14 days of age, but few cases have been reported in girls younger than 16 yr of age.

The *gonadoblastoma* occurs exclusively in dysgenetic gonads, particularly in phenotypic females who have a Y chromosome in their genotype (46,XY; 45,X/46,XY; 45,X/46,X fra). The tumor may be bilateral. Virilization occurs with some but not all tumors. The clinical features are the same as those seen in patients with virilizing adrenal tumors and include accelerated growth, acne, clitoral enlargement, and growth of sexual hair. A palpable, abdominal mass is found in only about 50% of patients. Plasma levels of testosterone and androstenedione are elevated, and those of gonadotropins are suppressed. Ultrasonography, CT, and MRI usually localize the lesion. The dysgenetic gonad of phenotypic females with a Y chromosome should be removed prophylactically. When a unilateral tumor is removed, the contralateral dysgenetic gonad should also be removed. In an immunohistochemical study of two gonadoblastomas, expression of *WT1*, *p53*, and *MIS* as well as inhibin were all demonstrated.

Virilizing manifestations occur occasionally in girls with *juvenile granulosa cell tumors*. Adrenal rests and hilus cell tumors rarely lead to virilization. Activating mutations of G protein genes have been described in ovarian (and testicular) tumors. *GSF* mutations, usually seen in gonadal tumors associated with

McCune-Albright syndrome, were also noted in four of six Leydig cell tumors (three ovarian, one testicular). Two granulosa cell tumors and one thecoma of 10 ovarian tumors studied were found to have *GIP-2* mutations.

Sertoli-Leydig cell tumors, rare sex cord/stromal neoplasms, comprise less than 1% of ovarian tumors. In one 12 mo old with Sertoli-Leydig cell tumor presenting with isosexual precocity the only detectable tumor marker was the serum inhibin level, with elevations in both A and B subunits. Of 102 consecutive patients who underwent surgery because of ovarian masses over a 15-yr period the presenting symptoms were acute abnormal peak in 56% and abdominal or pelvic mass in 22%. Of 9 children whose cause for surgery was presumed malignancy, 3 had dysgerminomas, 2 had teratomas, 2 had juvenile granulose cell tumors, 1 had a Sertoli-Leydig cell tumor, and 1 had a yolk sac tumor.

Chapter 582 - Intersex

Intersex, formerly known as hermaphroditism, implies a discrepancy between the morphology of the gonads and that of the external genitals. Many chromosomal aberrations resulting in ambiguity of the external genitals are discussed earlier in this section. In this chapter, conditions of aberrant sexual differentiation that are imposed on the XX or XY genotype—46,XX intersex and 46,XY intersex—are discussed (Box 582–1). An increasing number of such conditions are understood through advances in the knowledge about molecular biology of normal sexual differentiation. The category of true gonadal intersex, previously known as true hermaphroditism, with few exceptions, is still a poorly understood heterogeneous group of disorders.

Sexual Differentiation (see also Chapter 576).

In normal differentiation, the final form of all sexual structures is consistent with normal sex chromosomes (either XX or XY). A 46,XX complement of chromosomes as well as genetic factors such as DAX-1 and the signaling molecule WNT-4 are necessary for the development of normal ovaries. Development of the male phenotype is even more complex. It requires a Y chromosome and, specifically,

XX/XY chimeras

an intact *SRY* gene, which, in association with other genes such as *SOX9, SF1*, and *WT1*, and more (see Chapter 576), directs the undifferentiated gonad to become a testis. Aberrant recombinations may result in X chromosomes carrying *SRY*, resulting in XX males, or Y chromosomes that have lost *SRY*, resulting in XY females.

Anti-müllerian hormone (AMH) also known as müllerian-inhibiting substance, the first testicular hormone produced at 6–7 wk of gestation, causes the müllerian ducts to regress; in its absence, they persist. AMH activation in the testes may require the *SF1* gene for activation. By about 8 wk of gestation, the Leydig cells of the testis begin to produce testosterone. During this critical period of male differentiation, testosterone secretion is stimulated by placental human chorionic gonadotropin (hCG), which peaks at 8–12 wk. In the latter half of pregnancy, lower levels of testosterone are maintained by luteinizing hormone secreted by the fetal pituitary. Testosterone initiates virilization of the wolffian duct into the epididymis, vas deferens, and seminal vesicle. Development of the external genitals also requires dihydrotestosterone (DHT), an active metabolite of testosterone. DHT is necessary to fuse the genital folds to form

the penis and scrotum. A functional androgen receptor, controlled by an X-linked gene, is required for testosterone and DHT to produce these virilizing changes.

In the XX fetus with normal long and short arms of the X chromosome, the bipotential gonad develops into an ovary by about the 10th–11th wk. This occurs only in the absence of *SRY*, testosterone, and AMH and requires a normal gene in the *DSS* locus DAX-1, and the WNT-4 molecule. The female phenotype develops independently of the fetal gonads, but maleness is imposed on a basically female potential by the hormones of the fetal testis. Estrogen is unnecessary for normal

prenatal sexual differentiation, as demonstrated by 46,XX patients with aromatase deficiency and by mice without estradiol receptors.

582.1 46,XX Intersex (46,XX with Virilization)

In this condition, formerly referred to as female pseudohermaphroditism, the genotype is XX and the gonads are ovaries, but the external genitals are virilized. Because there is no AMH (the gonads are ovaries not testes), the uterus, tubes, and ovaries develop. The varieties and causes of this condition are relatively few. Most instances result from exposure of the female fetus to excessive exogenous or endogenous androgens during intrauterine life. The changes consist principally of virilization of the external genitals (clitoral hypertrophy and labioscrotal fusion).

Congenital Adrenal Hyperplasia (see Chapter 570.1).

This is the most common cause of genital ambiguity and 46,XX intersex. Females with the 21-hydroxylase and 11-hydroxylase defects are the most highly virilized, although minimal virilization also occurs with the type II 3ß-hydroxysteroid dehydrogenase defect. Salt losers tend to have greater degrees of virilization than do non–salt-losing patients. Masculinization may be so intense that a complete penile urethra results, and the condition may mimic a male with cryptorchidism (see Chapter 570.1).

Aromatase Deficiency.

In genotypic females, aromatase deficiency during fetal life leads to 46,XX intersex and results in hypergonadotropic hypogonadism at puberty because of ovarian failure to synthesize estrogen (see Section 4 and Fig. 568–1).

Two 46,XX infants had enlargement of the clitoris and posterior labial fusion at birth. In one instance, maternal serum and urinary levels of estrogen were very low and serum levels of androgens were high. Cord serum levels of estrogen were also extremely low, but those of androgen were elevated. The second patient also had virilization of unknown cause since birth, but the aromatase deficiency was not diagnosed until 14 yr of age, when she had further virilization and failed to go into puberty. At that time, she had elevated levels of gonadotropins and androgens but low estrogen levels, and ultrasonography revealed large ovarian cysts bilaterally. These two patients demonstrate the important role of aromatase in the conversion of androgens to estrogens. Additional female and male patients with aromatase deficiency due to mutations in the $P450_{arom}$ *(CYP19)* gene are known. Two siblings were described. The 28-yr-old XY proband was 177.6?cm tall (+2.5?SD) after having received hormonal replacement therapy; her 24-yr-old brother was 204?cm tall (+3.7?SD), and had a bone age of 14 yr. Low-dose estradiol replacement, carefully adjusted to maintain normal age-appropriate levels, may be indicated for affected females even prepubertally.

Glucocorticoid Receptor Gene Mutation.

A 9-yr-old girl with 46,XX intersex, thought to be due to 21-OHase deficiency (congenital adrenal hyperplasia) since the age of 5 yr, had elevated cortisol levels at baseline and after dexamethasone, hypertension, and hypokalemia suggestive of the diagnosis of generalized glucocorticoid resistance. A novel homozygous mutation in exon 5 of the glucocorticoid receptor was demonstrated. In this Brazilian family the condition was autosomal recessive.

Virilizing Maternal Tumors.

Rarely, the female fetus has been virilized during fetal life by a maternal androgen-producing tumor. In a few cases, the lesion was a benign adrenal adenoma, but all others were ovarian tumors, particularly androblastomas, luteomas, and Krukenberg tumors. Maternal virilization may be manifested by enlargement of the clitoris, acne, deepening of the voice, decreased lactation, hirsutism, and elevated levels of androgens. In the infant, there is enlargement of the clitoris of varying degrees, often with labial fusion. Mothers of children with unexplained 46,XX intersex should undergo measurements of their own levels of plasma testosterone, dehydroepiandrosterone sulfate, and androstenedione.

Administration of Androgenic Drugs to Women During Pregnancy.

Testosterone and 17-methyltestosterone have been reported to cause 46,XX intersex in some instances. The greatest number of cases has resulted from the use of certain progestational compounds for the treatment of threatened abortion. These progestins have been replaced by nonvirilizing ones.

Infants with virilization and 46,XX chromosomes and caudal anomalies have been reported for whom no virilizing agent could be identified. In such instances, the disorder is usually associated with other congenital defects, particularly of the urinary and gastrointestinal tracts. Y-specific DNA sequences, including SRY, are absent. In one case, a scrotal raphe and elevated testosterone levels were found, but the cause remains unknown.

582.2 46,XY Intersex (46,XY with Undervirilization)

In this condition, formerly referred to as male pseudohermaphroditism, the genotype is XY, but the external genitals are incompletely virilized, ambiguous, or completely female. When gonads can be found, they are invariably testes; their development may range from rudimentary to normal. Because the process of normal virilization in the fetus is so complex, it is not surprising that there are many varieties of undervirilized 46,XY individuals.

DEFECTS IN TESTICULAR DIFFERENTIATION

The first step in male differentiation is conversion of the indifferent gonad to a testis. In the XY fetus, if there is a deletion of the *short arm of the Y chromosome* or of the *SRY* gene, male differentiation does not occur. The phenotype is female; müllerian ducts are well developed because of the absence of AMH, but gonads consist of undifferentiated streaks. By contrast, even extreme deletions of the *long arm of the Y chromosome* (Yq-) have been found in normally developed males, most of whom are azoospermic and have short stature, indicating that the long arm of the Y chromosome normally has genes that prevent these manifestations. In other

syndromes in which the testes fail to differentiate, Y chromosomes are morphologically normal.

Denys-Drash Syndrome.

The constellation of nephropathy with ambiguous genitals and bilateral Wilms tumor are the major characteristics of this syndrome. Most reported cases have been 46,XY. Müllerian ducts are often present, indicating a global deficiency of fetal testicular function. Patients with 46,XX karyotype have normal external genitals. The onset of proteinuria in infancy progresses to nephrotic syndrome and end-stage renal failure by 3 yr of age, with focal or diffuse mesangial sclerosis being the most consistent histopathologic finding. Wilms tumor usually develops in children younger than 2 yr of age and is frequently bilateral. Gonadoblastomas have been reported.

Several mutations of the Wilms tumor gene *(WT1)*, located on chromosome 11p13, have been found. *WT1* functions as a tumor-suppressor gene and transcriptional factor and is expressed in the genital ridge and fetal gonads. Nearly all reported mutations have been near or within the zinc finger coding region. One report found a zinc finger domain mutation in the *WT1* alleles of a patient without any genitourinary abnormalities, suggesting that some cases of sporadic Wilms tumor may carry the *WT1* mutation. Different mutations of the *WT1* gene have been described in Fraser syndrome, a condition of nonspecific focal and segmental glomerulosclerosis, 46,XY gonadal dysgenesis, and frequent gonadoblastoma, without Wilms tumor.

WAGR Syndrome.

This acronymic contiguous gene syndrome consists of *W*ilms tumor, *a*niridia, *g*enitourinary malformations, and *r*etardation. These children have a deletion of one copy of chromosome 11p13, which may be visible on karyotype analysis. The deleted region encompasses the aniridia gene *(PAX6)* and the Wilms tumor suppressor gene *(WT1)*. Only 46,XY males have genital abnormalities, ranging from cryptorchidism to severe deficiency of virilization. Gonadoblastomas have developed in the dysgenetic gonads. Wilms tumor usually occurs by 2 yr of age. Three cases also had unexplained obesity, raising the question of an obesity-associated gene in this region of chromosome 11.

Camptomelic Syndrome (see Chapter 692).

This form of short-limbed dysplasia is characterized by anterior bowing of the femur and tibia and by malformations of other organs. It is usually lethal in early infancy. About 75% of reported 46,XY patients exhibit sex reversal with a completely female phenotype; the external and internal genitals are female. Some 46,XY patients have ambiguous genitals. The gonads appear to be ovaries but histologically may contain elements of ovaries and testes.

The gene responsible for the condition is *SOX9* (*SRY*-related HMG-bo*x* gene) and is on 17q24-q25. This gene is structurally related to *SRY* and also directly regulates the type II collagen gene *(COL2A1)* development. The same mutations may result in different gonadal phenotypes. Gonadoblastoma was reported in a patient with this condition. The inheritance is autosomal dominant. Adrenal insufficiency and 46,XY gonadal dysgenesis was described in a patient with mutation of the *SF1* gene.

46,XY sex reversal has been described in patients with deletions of parts of autosomal loci on chromosomes 2q, 9p, and 10q.

XY Pure Gonadal Dysgenesis (Swyer Syndrome).

The designation “pure” distinguishes this condition from forms of gonadal dysgenesis that are of chromosomal origin and associated with somatic anomalies. Affected patients have normal stature and a female phenotype, including vagina, uterus, and fallopian tubes, but at pubertal age, breast development and menarche fail to occur. None of the defects associated with 45,X children is present. Patients present at puberty with hypergonadotropic primary amenorrhea. Familial cases suggest an X-linked or a sex-limited dominant autosomal transmission. Most of the patients examined have had mutations of the *SRY* gene. None had a *SOX9* gene mutation. The gonads consist of almost totally undifferentiated streaks despite the presence of a cytogenetically normal Y chromosome. The primitive gonad cannot accomplish any testicular function, including suppression of müllerian ducts. There may be hilar cells in the gonad capable of producing some androgens; accordingly, some virilization, such as clitoral enlargement, may occur at the age of puberty. The streak gonads may undergo neoplastic changes, such as gonadoblastomas and dysgerminomas and should be removed shortly after diagnosis, regardless of age.

Pure gonadal dysgenesis also occurs in XX individuals (see Chapter 580.).

XY Gonadal Agenesis Syndrome (Embryonic Testicular Regression Syndrome).

In this rare syndrome, the external genitals are slightly ambiguous but more nearly female. Hypoplasia of the labia, some degree of labioscrotal fusion, a small clitoris-like phallus, and a perineal urethral opening are present. No uterus, no gonadal tissue, and usually no vagina can be found. At the age of puberty, no sexual development occurs and gonadotropin levels are elevated. Most children have been reared as females. In several patients with XY gonadal agenesis in whom no gonads could be found on exploration, significant rises in testosterone followed stimulation with hCG, indicating Leydig cell function somewhere. Siblings with the disorder are known.

It is presumed that testicular tissue was active long enough during fetal life for AMH to inhibit development of müllerian ducts but not long enough for testosterone production to result in virilization. In one patient, no deletion of the Y chromosome was found using Y-specific DNA probes. Testicular degeneration seems to occur between the 8th and the 12th fetal wk. Regression of the testis before the 8th wk of gestation results in Swyer syndrome; between the 14th and the 20th wk of gestation, it results in the rudimentary testis syndrome; and after the 20th wk, it results in anorchia.

In *bilateral anorchia*, testes are absent, but the male phenotype is complete; it is presumed that tissue with fetal testicular function was active during the critical period

of genital differentiation but that sometime later it was damaged. Bilateral anorchia in identical twins and unilateral anorchia in identical twins and in siblings suggest a genetic predisposition. Coexistence of anorchia and the gonadal agenesis syndrome in a sibship is evidence for a relationship between the disorders. *SRY* defects have not yet been reported for patients with anorchia.

A retrospective review of urologic explorations revealed absent testes in 21% of 691 testes. Of those, 73% had blind-ending cord structures with the suggested site of the vanishing testes being the inguinal canal (59%), the abdomen (21%), superficial inguinal ring (18%), and scrotum (2%). It was suggested that the presence of cord structures on laparoscopy should prompt inguinal exploration because viable testicular tissue was found in four of these children. No hormonal data (hCG stimulation tests, AMH levels) were reported.

DEFECTS IN TESTICULAR HORMONES

Five genetic defects have been delineated in the enzymatic synthesis of testosterone by fetal testis, and a defect in Leydig cell differentiation has been described. These defects produce 46,XY males with inadequate masculinization (Fig. 582–1). Because levels of testosterone are normally low before puberty, an hCG stimulation test must be used in children to assess the ability of the testes to synthesize testosterone.

Leydig Cell Aplasia.

Patients with aplasia or hypoplasia of the Leydig cells usually have female phenotypes, but there may be mild virilization. Testes, epididymis, and vas are present; the uterus and fallopian tubes are absent. There are no secondary sexual changes at puberty; pubic hair may be normal. Plasma levels of testosterone are low and do not respond to hCG; luteinizing hormone (LH) levels are elevated. The Leydig cells of the testes are absent or markedly deficient. The defect may involve a lack of receptors for LH. In children, hCG stimulation is necessary to differentiate the condition from the androgen insensitivity syndromes (AIS). There is male-limited autosomal recessive inheritance. The human LH receptor is a member of the G protein–coupled superfamily of receptors that contains seven transmembrane domains. Several inactivating mutations of the LH receptor have been described in males with hypogonadism suspected of having Leydig cell hypoplasia or aplasia.

High serum LH and low follicle-stimulating hormone (FSH) were noted in one male with hypogonadism owing to a mutation in the gene for the ß-subunit of FSH (see Table 577–1]).

Figure 582.2-1 Biosynthesis of androgens. The *dotted lines* indicate enzymatic defects associated with male pseudohermaphroditism. The *vertical dotted line* indicates a defect in 3ß-hydroxysteroid dehydrogenase. A single polypeptide, P450c17, catalyzes both 17a-hydroxylase and 17,20-lyase activities.

Lipoid Adrenal Hyperplasia (also see Chapter 570).

The most severe form of congenital adrenal hyperplasia derives its name from the appearance of the enlarged adrenal glands resulting from accumulation of cholesterol and cholesterol esters. It was previously thought to be due to defective P450scc activity, the enzyme responsible for side-chain cleavage of a carbon unit from cholesterol to form pregnenolone. It has now been proved that it is due to diminished delivery of the substrate cholesterol to the inner mitochondrial membrane and to the P450scc system. That process is regulated by steroidogenic acute regulatory protein (StAR), mutations of which were documented in children with lipoid adrenal hyperplasia.

All serum steroid levels are low or undetectable, whereas corticotropin and plasma renin levels are elevated. The phenotype is female in genetic females and males; genetic males have no müllerian structures because the testes can produce normal AMH but no steroid. These children present with acute adrenal crisis and salt wasting in infancy. Most patients are 46,XY. In a few patients, ovarian steroidogenesis is present at puberty.

The regulatory role of StAR-independent steroidogenesis is illustrated by 46,XX 4-mo-old twins with lipoid adrenal hyperplasia. One died at 15 mo because of cardiac complications related to coarctation of the aorta. The adrenal glands had characteristic lipid deposits. The surviving twin had spontaneous puberty with feminization at 11.5 yr with menarche at 13.8 yr. When restudied at the age of 15 yr, a homozygous frameshift-inactivating mutation in her StAR gene was discovered. This and the fact that she survived as an infant until 4 mo of age without replacement therapy with detectable serum aldosterone levels supports the hypothesis that StAR-independent steroidogenesis was able to proceed until enough intracellular lipid accumulated to destroy steroidogenic activity. Partial defects in only partially virilized males and delayed onset of salt wasting have been described. Complete P450scc defects may be incompatible with life because only this enzyme can convert cholesterol to pregnenolone, which then becomes progesterone, a hormone essential for the maintenance of normal mammalian pregnancy. Heterozygous mutation in P450scc was described in a 4 yr old with 46,XY sex reversal and late-onset form of lipoid adrenal hyperplasia. At 6–7 wk of gestation, when maternal corpus luteum progesterone synthesis stops, the placenta, which does not express StAR, produces progesterone by StAR-independent steroidogenesis using the P450scc enzyme system.

3ß-Hydroxysteroid Dehydrogenase Deficiency.

Males with this form of congenital adrenal hyperplasia (see Chapter 570) have various degrees of hypospadias, with or without bifid scrotum and cryptorchidism and, rarely, a complete female phenotype. Affected infants usually acquire salt-losing manifestations shortly after birth. Incomplete defects, occasionally seen in boys with premature pubarche, as well as late-onset nonclassic forms have been reported. These children have point mutations of the gene for type II 3ß-hydroxysteroid enzyme, resulting in impairment of steroidogenesis in the adrenals and gonads; the impairment may be unequal between adrenals and gonads. Normal pubertal changes in some boys could be explained by the normally present type I

3ß-hydroxysteroid dehydrogenase present in many peripheral tissues. Infertility is not infrequent. More than 31 different mutations are reported. There is no correlation between degree of salt wasting and degree of phenotypic abnormality.

Deficiency of 17-Hydroxylase/17,20 Lyase.

A single enzyme (P450c17) encoded by a single gene on chromosome 10q24.3 has both 17-hydroxylase and 17,20 lyase activities in adrenal and gonadal tissues (see Chapter 570). Many different genetic lesions have been reported. Genetic males usually present with a complete female phenotype or, less often, with various degrees of undervirilization from labioscrotal fusion to perineal hypospadias and cryptorchidism. Pubertal development fails to occur in both genetic sexes.

In the classic disorder, there is decreased synthesis of cortisol by the adrenals and of sex steroids by the adrenals and gonads (see Fig. 582–1 and Fig. 568–1). Levels of deoxycorticosterone (DOC) and corticosterone are markedly increased and lead to the hypertension and hypokalemia characteristic of this form of male pseudohermaphroditism. Although levels of cortisol are low, the elevated corticotropin and corticosterone levels maintain a eucorticoid state. The renin-aldosterone axis is suppressed because of the strong mineralocorticoid effect of elevated DOC. Virilization does not occur at puberty; levels of testosterone are low, and those of gonadotropins are increased. Because fetal production of AMH is normal, no müllerian duct remnants are present. In phenotypic XY females, gonadectomy and replacement therapy with hydrocortisone and sex steroids are indicated.

The defect follows autosomal recessive inheritance. Affected XX females are usually not detected until young adult life, when they fail to experience normal pubertal changes and are found to have hypertension and hypokalemia. This condition should be suspected in patients presenting with primary amenorrhea and hypertension whose chromosomal complement is either 46,XX or 46,XY.

Deficiency of 17-Ketosteroid Reductase.

This enzyme, also called 17ß-hydroxysteroid dehydrogenase (17ß-HSD), is the last in the testosterone biosynthetic pathway; it is necessary to convert androstenedione to testosterone and also dehydroepiandrosterone to androstenediol and estrone to estradiol. Enzymatic defects in fetal testicular tissue give rise to males with complete or near-complete female phenotype in 46,XY males. Müllerian ducts are absent, and a shallow vagina is present. The diagnosis is based on the ratio of testosterone to androstenedione; in prepubertal children, prior stimulation with hCG is necessary.

The defect is inherited in an autosomal recessive fashion. At least four different types of 17ß-HSD are recognized, each coded by a different gene or different chromosomes. Type III is the enzyme defect that is especially common in a highly inbred Arab population in Gaza. The gene for the disorder is at 9q22 and is expressed only in the testes, where it converts androstenedione to testosterone.

Most patients are diagnosed at puberty because of the failure to menstruate and virilization. Testosterone levels at puberty may approach normal, presumably as a result of peripheral conversion of androstenedione to testosterone; at this time, some patients spontaneously adopt a male gender role.

Type I 17ß-HSD, encoded by a gene on chromosome 17q21, converts estrone to estradiol and is found in placenta, ovary, testis, liver, prostate, adipose tissue, and endometrium. Type II, whose gene is on chromosome 16q24, has activities that are opposite to those of types I and III (convert testosterone to androstenedione and estrone to estradiol). Type IV is similar in action to type II. A late-onset form of 17-ketosteroid reductase deficiency presents as gynecomastia in young adult males.

Persistent Müllerian Duct Syndrome.

In this disorder, there is persistence of müllerian duct derivatives in otherwise completely virilized males. Cases have been reported in siblings and identical twins. Cryptorchidism is present in 80% of affected males; and during surgery for this or inguinal hernia, the condition is uncovered when a fallopian tube and uterus are found. The degree of müllerian development is variable and may be asymmetric. Testicular function is normal in most, but testicular degeneration has been reported. Some affected males acquire testicular tumors after puberty. In a study of 38 families, 16 families had defects in the AMH gene, located on the short arm of chromosome 19. They had low AMH levels. In 16 families with high AMH levels, the defect was in the AMH type II receptor gene, with 10/16 having identical 27-bp deletions on exon 10 in at least one allele.

Treatment consists of removal of as many of the müllerian structures as possible without causing damage to the testis, epididymis, or vas deferens.

DEFECTS IN ANDROGEN ACTION

In the following group of disorders, fetal synthesis of testosterone is normal and defective virilization results from inherited abnormalities in androgen action.

5a-Reductase Deficiency.

Decreased production of dihydrotestosterone (DHT) in utero results in severe ambiguity of the external genitals of the affected male fetus. Biosynthesis and peripheral action of testosterone are normal.

The phenotype most commonly associated with this condition results in boys who have a small phallus, bifid scrotum, urogenital sinus with perineal hypospadias, and a blind vaginal pouch. Testes are in the inguinal canals or labioscrotal folds and are normal histologically. There are no müllerian structures. Wolffian structures—the vas deferens, epididymis, and seminal vesicles—are present. Most affected patients have been identified as females. At puberty, virilization occurs; the phallus enlarges, the testes descend and grow normally, and spermatogenesis occurs. There is no gynecomastia. Beard growth is scanty, acne is absent, the prostate is small, and recession of the temporal hairline fails to occur. Virilization of the wolffian duct is caused by the action of testosterone itself, although masculinization of the urogenital sinus and external genitals depends on the action of DHT during the critical period of

fetal masculinization. Growth of facial hair and of the prostate also appears to be DHT dependent.

The adult height reached is close to that of the father and other male siblings. There is, however, significant phenotypic heterogeneity. This has led to a classification of such patients into five types of steroid 5a-reductase deficiency (SRD) ranging from complete female (type 5), to partial female (type 4), ambiguous (type 3), predominantly male with micropenis (type 2), and completely male phenotype without apparent undervirilization (type 1).

Several different gene defects leading to steroid 5a-reductase deficiency have been identified in the 5a-reductase type 2 gene, located on the short arm of chromosome 2, in patients from throughout the world. Familial clusters have been reported from the Dominican Republic, Turkey, Papua New Guinea, Brazil, Mexico, and the Middle East. There is no correlation between severity of the genetic defect and phenotype.

The disorder is inherited as an autosomal recessive trait but is limited to males; normal homozygous females with normal fertility indicate that in females DHT has no role in sexual differentiation or in ovarian function later in life. The clinical diagnosis should be made as early as possible in infancy; it should be distinguished from androgen insensitivity syndrome. The biochemical diagnosis is based on finding normal serum testosterone levels, normal or low DHT levels with markedly increased basal and, especially, hCG-stimulated testosterone:DHT ratios (>17), and high ratios of urinary etiocholanolone to androsterone and 5ß to 5a metabolites. Children with androgen insensitivity have normal hepatic 5a reduction and, thus, a normal ratio of tetrahydrocortisol to 5a-tetrahydrocortisol as opposed to those with SRD.

Most but, importantly, not all children reared as females in childhood have changed to male around the time of puberty. It appears that exposures to testosterone in utero, neonatally, and at puberty contribute to the formation of male gender identity. Much more needs to be learned about the influences of hormones such as androgens as well as the influences of cultural, social, psychologic, genetic, and other biologic factors in gender identity and behavior. Infants with this condition should be reared as boys whenever practical. Treatment of male infants with DHT results in phallic enlargement.

Androgen Insensitivity Syndromes.

The AIS compose the most common forms of male pseudohermaphroditism, occurring with a presumed frequency of 1/20,000 genetic males. This group of heterogeneous X-linked disorders is due to more than 150 different mutations in the androgen receptor gene, located

on Xq11-12: single point mutations resulting in amino acid substitutions or premature stop codons, frameshift and premature terminations, gene deletions, and splice site mutations.

CLINICAL MANIFESTATIONS.

The clinical spectrum of patients with AIS, all of whom have a 46,XY chromosomal complement, range from phenotypic females (in complete AIS) to males with various forms of ambiguous genitals and undervirilization (partial AIS, or clinical syndromes such as Reifenstein syndrome) to phenotypically normal-appearing males with infertility. In addition to normal 46,XY chromosomes, the presence of testes and normal or elevated testosterone levels are common to all such children.

In complete AIS, an extreme form of failure of virilization, genetic males appear female at birth and are invariably reared accordingly. The external genitals are female. The vagina ends blindly in a pouch, and the uterus is absent. In about one third of patients, unilateral or bilateral fallopian tube remnants are found. The testes are usually intra-abdominal but may descend into the inguinal canal; they consist largely of seminiferous tubules. Twin girls with inguinal hernias containing testes were described. At puberty, there is normal development of breasts, and the habitus is female, but menstruation does not occur and sexual hair is absent. Adult heights of these women are commensurate with those of normal males despite profound congenital deficiency of androgenic effects.

The testes of affected adult patients produce normal male levels of testosterone and DHT. Failure of normal male differentiation during fetal life reflects defective response to androgens at that time, but the absence of müllerian ducts indicates normal fetal testicular production of AMH. The absence of androgenic effects is caused by a striking resistance to the action of endogenous or exogenous testosterone at the cellular level.

Prepubertal children with this disorder are often detected when inguinal masses prove to be testes or when a testis is unexpectedly found during herniorrhaphy in a phenotypic female. About 1–2% of girls with an inguinal hernia prove to have this disorder. In infants, elevated gonadotropin levels should suggest the diagnosis. In adults, amenorrhea is the usual presenting symptom. In prepubertal children, the condition must be differentiated from other types of XY undervirilized males in which there is complete feminization. These include XY gonadal dysgenesis (Swyer syndrome), true agonadism, Leydig cell aplasia including LH receptor defects, and 17-ketosteroid reductase deficiency; all of these conditions, unlike complete AIS, are characterized by low levels of testosterone as neonates and during adult life and by failure to respond to hCG during the prepubertal years. Although patients with complete AIS present with unambiguously female external genitals at birth, those with partial AIS have a wide variety of phenotypic presentations ranging from perineoscrotal hypospadias, bifid scrotum, and cryptorchidism to extreme undervirilization appearing as clitoromegaly and labial fusion. Some forms of partial AIS have been known as specific syndromes. Patients with *Reifenstein syndrome* have incomplete virilization characterized by hypogonadism, severe hypospadias, and gynecomastia. *Gilbert-Dreyfuss* and *Lubs* are additional syndromes classified as partial AIS. In all cases, abnormalities in the androgen receptor gene have been identified.

DIAGNOSIS.

The diagnosis of patients with partial AIS may be particularly difficult in infancy. In some, especially those sufficiently virilized in infancy, the diagnosis is not suspected until puberty when there is inadequate virilization with lack of facial hair or voice change and the appearance of gynecomastia. Azoospermia and infertility are common. Increasingly, androgen receptor defects are being recognized in adults who have a small phallus and testes and infertility. A single amino acid substitution in the androgen receptor was reported in a large Chinese family in whom some affected members were fertile while others had gynecomastia and/or hypospadias.

TREATMENT AND PROGNOSIS.

In patients with complete AIS whose sexual orientation is unambiguously female, the testes should be removed as soon as they are discovered. Laparoscopic removal of Y-chromosome bearing gonads has been performed in patients with AIS and in those with gonadal dysgenesis. In one third of patients, malignant tumors, usually seminomas, develop by 50 yr of age. Several teenaged girls have acquired seminomas. Replacement therapy with estrogens is indicated at the age of puberty.

Normal breasts develop in affected girls who have not had their testes removed by the age of puberty. In these individuals, production of estradiol results from aromatase activity. The absence of androgenic activity also contributes to the feminization of these women.

The psychosexual and surgical management of patients with partial AIS is extremely complex and depends in large part on the presenting phenotype. Osteopenia is now recognized as a feature of AIS.

Molecular analyses have suggested that phenotype may depend in part on somatic mosaicism of the androgen receptor gene. This was based on the case of a 46,XY patient who had a premature stop codon in exon 1 of the *AR* gene but who also had evidence of virilization (pubic hair and clitoral enlargement) explained by the discovery of the wild-type alleles on careful examination of the sequencing gel. The presence of mosaicism shifts the phenotype to a higher degree of virilization than expected from the genotype of the mutant allele alone.

Genetic counseling is difficult in families with androgen receptor gene mutation. In addition to lack of genotype-phenotype correlations, there is a high rate (27%) of de novo mutations in families.

Sex hormone–binding globulin reduction after exogenous androgen administration (stanozolol) has been shown to correlate with the severity of the receptor defect and may become a useful clinical tool. Successful therapy with supplemental androgens has been reported in patients with partial AIS and various mutations of the androgen receptor in the DNA-binding domain and the ligand-binding domain.

Mutated androgen receptors are also reported in patients with spinal and bulbar muscular atrophy in whom clinical manifestations including testicular atrophy, infertility, gynecomastia, and elevated LH, FSH, and estradiol levels usually manifest between the 3rd–5th decades of life. Androgen receptor mutations have also been described in patients with prostate cancer.

UNDETERMINED CAUSES

Other XY undervirilized males display great variability of the external and internal genitals and various degrees of phallic and müllerian development. Testes may be histologically normal or rudimentary, or there may only be one. Even the newer techniques may find no recognized cause of intersex in a substantial number of children. Some ambiguity of genitals is associated with a wide variety of chromosomal aberrations, which must always be considered in the differential diagnosis, the most common being the 45,X/46,XY syndrome (see Chapter 580.1). It may be necessary to examine several tissues to establish mosaicism. Other complex genetic syndromes, many resulting from single gene mutations, are associated with varying degrees of ambiguity of the genitals, particularly in the male. These entities must be identified on the basis of the associated extragenital malformations.

Smith-Lemli-Opitz syndrome is an autosomal recessive disorder characterized by prenatal and postnatal growth retardation, microcephaly, ptosis, anteverted nares, broad alveolar ridges, syndactyly of the 2nd–3rd toes, and severe mental retardation (see Chapter 75.3). Genotypic males usually have genital ambiguity and, occasionally, complete sex reversal with female genital ambiguity or complete sex reversal with female external

---

genitals. Müllerian duct derivatives are usually absent. Affected 46,XX patients have normal genitals. Two types of Smith-Lemli-Opitz syndrome have been recognized: the classic form (type I) described earlier and the acrodysgenital syndrome, which is usually lethal within 1 yr and is associated with severe malformations, postaxial polydactyly, and extremely abnormal external genitals (type II). Pyloric stenosis is associated with Smith-Lemli-Opitz syndrome type I and Hirschsprung disease with type II. Cleft palate, skeletal abnormalities, and one case of a lipoma of the pituitary gland have been seen in type II cases.

Low plasma cholesterol with elevated 7-dehydrocholesterol, its precursor, are found in both types (see Chapter 75.3 for treatment).

46,XY Intersex subjects also have been described in siblings with the a-thalassemia/mental retardation syndrome.

582.3 True Gonadal Intersex

In true gonadal intersex, formerly known as true hermaphroditism, both ovarian and testicular tissues are present, either in the same or in opposite gonads. Affected patients have ambiguous genitals, varying from normal female with only slight enlargement of the clitoris to almost normal male external genitals.

About 70% of all patients have a 46,XX karyotype; 97% of affected African blacks

are 46,XX. Fewer than 10% of persons with true intersex are 46,XY. About 20% have 46,XX/46,XY mosaicism. Half of these are derived from more than one zygote and are chimeras (chi 46,XX/46,XY). The presence of paternal and both maternal alleles for some blood groups is demonstrated. A true gonadal intersex chimera, 46,XX/46,XY, was reported as resulting from embryo amalgamation after in vitro fertilization. Each embryo was derived from an independent, separately fertilized ovum.

Examination of 46,XX true gonadal intersex patients with Y-specific probes has detected fewer than 10% with a portion of the Y chromosome including the *SRY* gene. True gonadal intersex is usually sporadic, but a number of siblings have been reported. The cause of most cases of true gonadal intersex is unknown.

The most frequently encountered gonad in true gonadal intersex is an ovotestis, which may be bilateral; if unilateral, the contralateral gonad is usually an ovary but may be a testis. The ovarian tissue is normal, but the testicular tissue is dysgenetic. The presence and function of testicular tissue can be determined by measuring basal and hCG-stimulated testosterone levels and AMH levels. Patients who are highly virilized, have good testicular function, and have no uterus are usually reared as males. If a uterus exists, virilization is mild, and testicular function minimal, assignment of female sex may be indicated. Selective removal of gonadal tissue inconsistent with sex of rearing is indicated. In a few families, 46,XY true gonadal intersex subjects and 44,XX males have been in the same sibship.

Pregnancies with living offspring have been reported in 46,XX true intersex individuals reared as females, but only very few intersex males with true gonadal intersex have fathered children. About 5% of patients acquire gonadoblastomas, dysgerminomas, or seminomas.

Diagnosis and Management.

In the neonate, ambiguity of the genitals requires immediate attention to decide on the sex of rearing as early in life as possible. The family of the infant needs to be informed of the child's condition as early, completely, compassionately, and honestly as possible. Caution must be used to avoid feelings of guilt, shame, and discomfort. Guidance needs to be provided to alleviate both short-term and long-term concerns and allow the child to grow up in a completely supportive environment. The initial care is best provided by a team of professionals that include neonatologists and pediatric specialists, endocrinologists, radiologists, urologists, psychologists, and geneticists, all of whom remain focused foremost on the needs of the child. Management of the potential psychologic upheaval that these disorders can generate in the child or the family is of paramount importance and requires physicians and other health care professionals with sensitivity, training, and experience in this field.

While awaiting the results of chromosomal analysis, pelvic ultrasonography or MRI is indicated to determine the presence of a uterus and ovaries. Presence of a uterus and absence of palpable gonads usually suggests a virilized XX female. A search for the source of virilization should be undertaken; this includes studies of adrenal hormones to rule out varieties of congenital adrenal hyperplasia, and studies of androgens and estrogens occasionally may be necessary to rule out aromatase deficiency. Virilized XX females are generally reared as females even when highly virilized.

The absence of a uterus, with or without palpable gonads, almost always indicates an undervirilized male and an XY karyotype. Measurements of levels of gonadotropins, testosterone, AMH, and DHT are necessary to determine whether testicular production of androgen is normal. Undervirilized males who are totally feminized may be reared as females. However, certain significantly feminized infants, such as those with 5a-reductase deficiency, should be reared as males because these children virilize normally at puberty. An infant with a comparable degree of feminization resulting from an androgen receptor defect is best reared as a female. Infants with 45,XX/46,XY karyotype whose phenotype varies from almost completely male to completely female are usually reared as females because they are generally short in stature and have a uterus; they require gonadectomy.

When receptor disorders are suspected in the XY male with a small phallus (micropenis), a course of three monthly intramuscular injections of testosterone enanthate (25–50?mg) may assist in the differential diagnosis as well as in treatment.

In some mammals, the female exposed to androgens prenatally or in early postnatal life exhibits nontraditional sexual behavior in adult life. Most, but not all, girls who have undergone fetal masculinization from congenital adrenal hyperplasia or from maternal progestin therapy have no such problems in sexual identity, although during childhood they may appear to prefer male playmates and activities over female playmates and feminine play with dolls in mothering roles.

Advances in visualization procedures, hormonal assays, molecular methodology, as well as surgical techniques should make for more rapid, accurate, and appropriate diagnosis and management of the infant and child with intersex. It has been thought that it is more feasible to reconstruct the external genitals to create a functional female, particularly when a vagina is present, than to create a functional male phallus. Hence, in the absence of reasonable prospects for a well-functioning male phallus, the intersex infants have in the past always been assigned a female gender. Considerable controversy currently exists regarding these decisions. A poorly functioning female external genital system may be no better then a poorly functioning male phallus. In addition, sexual functioning is to a large extent more dependent on other neurohormonal and behavioral factors then the physical appearance and functional ability of the genitals. This concept is given added support by a case report of a 46,XY subject whose penis was accidentally ablated and was subsequently reared as a female. At puberty this individual switched to male and continues to successfully live as such.

Similarly, controversy exists regarding the timing of the performance of invasive and definitive procedures, such as surgery. Whenever possible without endangering the physical or psychological health of the child, an expert multidisciplinary team should consider deferring elective surgical repairs and gonadectomies until the child can participate in the informed consent for

the procedure. Long-term prospective as well as retrospective science- and evidence-based studies in sufficient numbers of individuals born with intersex are necessary to evaluate their anatomic, psychosexual, social, as well as functional status.

The pediatrician and pediatric endocrinologist, along with the appropriate additional specialists, should provide ongoing compassionate, supportive care to the patient and the patient's family throughout childhood, adolescence, and even young adulthood. Support groups are available for patients and families with many of the conditions discussed.

Chapter 583 - Diabetes Mellitus

583.1 Introduction and Classification

Diabetes mellitus (DM) is a common, chronic, metabolic syndrome characterized by hyperglycemia as a cardinal biochemical feature. The major forms of diabetes are divided into those caused by deficiency of insulin secretion due to pancreatic ß-cell damage (type 1 DM), and those that are a consequence of insulin resistance occurring at the level of skeletal muscle, liver, and adipose tissue, with various degrees of ß-cell impairment (type 2 DM). Type 1 DM is the most common endocrine-metabolic disorder of childhood and adolescence, with important consequences for physical and emotional development. Individuals with type 1 DM confront serious lifestyle alterations that include an absolute daily requirement for exogenous insulin, the need to monitor their own glucose control, and the need to pay attention to dietary intake. Morbidity and mortality stem from acute metabolic derangements and from long-term complications (usually in adulthood) that affect small and large vessels resulting in retinopathy, nephropathy, neuropathy, ischemic heart disease, and arterial obstruction with gangrene of the extremities. The acute clinical manifestations are due to hypoinsulinemic hyperglycemic ketoacidosis. Autoimmune mechanisms are factors in the genesis of type 1 DM; the long-term complications are related to metabolic disturbances (hyperglycemia).

DM is not a single entity but rather a heterogeneous group of disorders in which there are distinct genetic patterns as well as other etiologic and pathophysiologic mechanisms that lead to impairment of glucose tolerance. A classification of diabetes and other categories of glucose intolerance is presented in Table 583–1 . Three major forms of diabetes and several forms of carbohydrate intolerance are identified.

Type 1 Diabetes Mellitus.

Formerly called insulin-dependent diabetes mellitus (IDDM) or juvenile diabetes, type 1 DM is characterized by low or absent levels of endogenously produced insulin and dependence on exogenous insulin to prevent development of ketoacidosis, an acute life-threatening complication of type 1 DM. The natural history includes preketotic, non– insulin-dependent phases both before and after the initial diagnosis. The onset occurs predominantly in childhood, with median age of 7 to 15 yr, but it may present at any age. Type 1 DM is characterized by autoimmune destruction of pancreatic islet ß cells. Both genetic susceptibility and environmental factors contribute to the pathogenesis of type. Susceptibility to type 1 DM is genetically controlled by alleles of the major histocompatability complex (MHC) class II genes expressing human leukocyte antigens (HLAs). It is also associated with autoantibodies to islet cell cytoplasm (ICA), insulin (IAA), antibodies to glutamic acid decarboxylase (GADA or GAD65), and ICA512 (IA2). Type 1 DM is associated with other autoimmune diseases such as thyroiditis, celiac disease, multiple sclerosis, and Addison disease. In some children and adolescents with apparent type 1 DM, the ß-cell destruction is not immune-mediated. This subtype of diabetes occurs in patients of African or Asian origin and is distinct from known causes of ß-cell destruction,

TABLE 583.1-1 -- Etiologic Classifications of Diabetes Mellitus

Type I diabetes[*] (ß-cell destruction, usually leading to absolute insulin deficiency)	*Drug- or chemical-induced*
	Vacor
	Pentamidine
Immune mediated	Nicotinic acid
Idiopathic	Glucocorticoids
Type II diabetes[*] (may range from predominantly insulin resistance with relative insulin deficiency to a predominantly secretory defect with insulin resistance)	Thyroid hormone
	Diazoxide
	ß-Adrenergic agonists
	Thiazides
	Dilantin

Other specific types	ß-Interferon
Genetic defects of ß-cell function	Others—cyclosporine, tacrolimus
Chromosome 12, HNF-1a (formerly MODY-3)	*Infections*
	Congenital rubella
Chromosome 7, glucokinase (formerly MODY-2)	Cytomegalovirus
	Others—hemolytic uremic syndrome
Chromosome 20, HNF-4a (formerly MODY-1)	
	Uncommon forms of immune-mediated diabetes
Mitochondrial DNA	
Others	“Stiff-man” syndrome
Genetic defects in insulin action	Cytomegalovirus
Type A insulin resistance	Others
Leprechaunism	*Other genetic syndromes sometimes associated with diabetes*
Rabson-Mendenhall syndrome	
Lipoatrophic diabetes	Down syndrome
Others	Klinefelter syndrome
Diseases of the exocrine pancreas	Turner syndrome
Pancreatitis	Wolfram syndrome

Trauma, pancreatectomy	Friedreich ataxia
Neoplasia	Huntington chorea
Cystic fibrosis	Laurence-Moon-Biedl syndrome
Hemochromatosis	
Fibrocalculous pancreatopathy	Myotonic dystrophy
Pancreatic resection	Porphyria
Others	Prader-Willi syndrome
Endocrinopathies	Others
Acromegaly	**Gestational diabetes mellitus**
Cushing disease	**Neonatal diabetes mellitus**
Glucagonoma	Transient—without recurrence
Pheochromocytoma	Transient—recurrence 7–20 yr later
Hyperthyroidism	Permanent from onset
Somatostatinoma	
Aldosteronoma	
Others	

** Patients with any form of diabetes may require insulin treatment at some stage of the disease. Such use of insulin does not, of itself, classify the patient.*

which include drugs or chemicals, viruses, mitochondrial gene defects, pancreatectomy, and ionizing radiation. These individuals may present with ketoacidosis but have extensive periods of remission with variable insulin deficiency, similar to patients with type 2 DM.

Type 2 Diabetes Mellitus.

The children and adolescents with this type of diabetes are usually obese but are not insulin-dependent and infrequently develop ketosis. Some may develop ketosis

during severe infections or other stresses and may then need insulin for correction of symptomatic hyperglycemia. This category includes the most prevalent form of diabetes in adults, which is characterized by insulin resistance and often a progressive defect in insulin secretion. This type of diabetes was formerly known as adult-onset diabetes mellitus, non–insulin-dependent diabetes mellitus (NIDDM), or maturity-onset diabetes of the young (MODY).

The presentation of type 2 DM is typically more insidious than that with type 1 DM. In contrast to patients with type 1 DM who are usually ill at the time of diagnosis, children with type 2 DM often seek medical care because of excessive weight gain and fatigue as a result of insulin resistance and/or incidental finding of glycosuria during routine physical examination. A history of polyuria and polydipsia is relatively uncommon in these patients. The incidence of type 2 DM in children has increased by more than 10-fold in many diabetes centers, in part as a result of the epidemic of childhood obesity. Pediatric type 2 DM may account for as many as 30% of the new cases of diabetes, especially in obese African and Mexican American adolescents. *Acanthosis nigricans* (dark pigmentation of skin creases/flexural areas), a sign of insulin resistance, is present in the majority of patients with type 2 DM and is accompanied by a relative hyperinsulinemia at the time of the diagnosis (see Chapter 642). However, the serum insulin elevation is usually disproportionately lower than that of age-, weight-, and sex-matched nondiabetic children and adolescents, suggesting a state of insulin insufficiency. In some individuals, it may represent slowly evolving type 1 DM.

In some children with strong family history of type 2 DM, impaired glucose tolerance may occur in a pattern implying dominant inheritance. This pattern of diabetes has been termed *maturity-onset diabetes of the young* (MODY) and may require insulin treatment. In MODY, there is no apparent autoimmune destruction of ß cells and no association with HLAs. This subclass of type 2 DM consists of specific genetic disorders involving mutations in the gene encoding pancreatic ß-cell and liver glucokinase (GK) or in the nuclear transcription factors hepatocyte nuclear factor (HNF)-4a or hepatic nuclear factor (HNF)-1a. A defect in the gene regulating glucose transport into the pancreatic ß cell, GLUT-2 transporter, may be responsible for other forms of type 2 DM. The genetic basis of type 2 DM also includes defects in glycogen synthase, insulin receptors, Rad (Ras associated with diabetes), and possibly apolipoprotein C-III.

Other Specific Types of Secondary Diabetes.

Examples include diabetes secondary to exocrine pancreatic diseases (e.g., cystic fibrosis), endocrine diseases other than pancreatic diseases (e.g., Cushing syndrome), and ingestion of certain drugs or poisons (e.g., the rodenticide Vacor). Certain genetic syndromes, including those with abnormalities of the insulin receptor, also are included in this category. There are no associations with HLAs, autoimmunity, or islet cell antibodies among the entities in this subdivision.

Table 583–2 details the current criteria for the diagnosis of DM. It should be noted that a fasting blood glucose that exceeds 126?mg/dL (7.0?mM) is the accepted criterion for diagnosing diabetes.

TABLE 583.1-2 -- Diagnostic Criteria for Impaired Glucose Tolerance and Diabetes Mellitus

Impaired Glucose Tolerance (IGT)	**Diabetes Mellitus (DM)**
Fasting glucose 110–125?mg/dL (6.1–7.0?mmol/L)	Symptoms* of DM plus random plasma glucose =200?mg/dL (11.1?mmol/L)
	or
2-hr plasma glucose during the OGTT <200?mg/dL (11.1?mmol/L) but =140?mg/dL	Fasting plasma glucose =126?mg/dL (7.0?mmol/L)
	or
	2-hr plasma glucose during the OGTT =200?mg/dL

OGTT, oral glucose tolerance test.

From Report of the Expert Committee on the Diagnosis and Classification of Diabetes Mellitus. Diabetes Care 1999; 20(Suppl 1):S5.

**Symptoms include polyuria, polydipsia, and unexplained weight loss with glucosuria and ketonuria.*

Impaired Glucose Tolerance.

The term *impaired glucose tolerance* (IGT) refers to a metabolic stage that is intermediate between normal glucose homeostasis and diabetes. A fasting glucose concentration of 109?mg/dL (6.1?mmol/L) is the upper limit of “normal.” This choice is near the level above which acute-phase insulin secretion is lost in response to intravenous administration of glucose and is associated with a progressively greater risk of the development of microvascular and macrovascular complications.

Many individuals with IGT are euglycemic in their daily lives and may have normal or nearly normal glycated hemoglobin levels. Individuals with IGT often manifest hyperglycemia only when challenged with the oral glucose load used in the standardized oral glucose tolerance test.

In the absence of pregnancy, IGT is not a clinical entity but rather a risk factor for future diabetes and cardiovascular disease. This may be observed as an intermediate stage in any of the disease processes listed in Table 583–1 . IGT is associated with the *insulin resistance syndrome* (also known as syndrome X or the metabolic syndrome), which consists of insulin resistance, compensatory hyperinsulinemia to maintain glucose homeostasis, obesity (especially abdominal or visceral obesity), dyslipidemia of the high-triglyceride or low-high-density lipoprotein type, or both, and hypertension. Insulin resistance is directly involved in the pathogenesis of type 2 DM. IGT appears as a risk factor for this type of diabetes at least in part because of its correlation with insulin resistance. The diagnostic criteria for IGT are presented in Table 583–2 .

583.2 Type 1 Diabetes Mellitus (Immune Mediated)

Epidemiology: Genetics and Environment.

The incidence of type 1 DM is rapidly increasing in specific regions and shows a trend toward earlier age of onset. The incidence of type 1 DM is highly variable among different ethnic groups. The overall age-adjusted incidence of type 1 DM varies from 0.7/100,000 per year in Karachi (Pakistan) to about 40/100,000 per year in Finland (Fig. 583–1). This represents more than a 400-fold variation in the incidence among about 100 populations analyzed. The increased incidence is seen in nations with a previous low incidence of autoimmune diabetes. For instance, the incidence of type 1 DM in Thailand increased markedly from 0.2/100,000 in 1984–1985 to 1.65/100,000 10 yr later. It is predicted that the overall incidence of type 1 DM will be about 40% higher in 2010 than in 1997.

Data from Western European diabetes centers suggest that the annual rate increase in type 1 DM incidence is 3–4%, whereas some central and eastern European countries demonstrate a significantly more rapid increase. The rates of increase in type 1 DM incidence as a function of age at onset are 6.3%, 3.1%, and 2.4% in age groups of children 0–4 yr, 5–9 yr, and 10–14 yr, respectively. In the United States, the prevalence of diabetes among school-aged children is about 1.9/1,000. The frequency, however, is highly correlated with increasing age; the range is 1 case/1,430 children at 5 yr of age to 1 in 360 children at 16 yr. Among African Americans, the occurrence of type 1 DM is between one third and two thirds of that seen in American whites. The annual incidence in the United States is about 14.9 new cases/100,000 of the child population. Girls and boys are almost equally affected; there is no apparent correlation with socioeconomic status. Peaks of presentation occur in two age groups: at 5–7 yr of age and at the time of puberty. Nonetheless, a growing number of patients are presenting between 1 and 2 yr of age. The first peak may correspond to the time of increased exposure to infectious agents coincident with the beginning of school; the latter may correspond to the pubertal growth spurt induced by gonadal steroids and the increased pubertal growth

Figure 583.2-1 Incidence rates of type 1 diabetes mellitus by region and country. (From LaPorte RA, et al: The DiaMond Project. *Pract Diabetes Int* 1995;12:93.)

hormone secretion (which antagonizes insulin). These possible cause-and-effect relationships remain to be proved.

GENES.

Genes for type 1 DM may provide both susceptibility to, and protection from, the disease. Although many chromosomal loci associated with such activities have been located, few true genes have been identified. The genetics of type 1 DM cannot be classified according to a specific model of inheritances. The most important genes are located within the MHC HLA class II region on chromosome 6p21, formally termed (IDDM1), accounting for about 60% genetic susceptibility for the disease; their specific contribution to the pathogenesis of type 1 DM remains unclear. The importance of the class II haplotypes not only depends on the well-known risk for disease associated with HLA-DR3 and HLA-DR4 but also on additional susceptibility associated with DQ a-chains and DQ ß-chains. Inheritance of HLA-DR3 or -DR4 antigens appears to confer a twofold to threefold increased risk for the development of type 1 DM. When both DR3 and DR4 are inherited, the relative risk for the development of diabetes is increased 7–10-fold. Analysis of DNA polymorphisms after digestion by specific restriction endonucleases has revealed further heterogeneity in the HLA-DR region among individuals with and without diabetes despite the possession of both DR3 or DR4 markers, suggesting a yet to be defined “susceptibility” locus within these markers.

In whites, at least one major susceptibility locus may reside in the $DQß_1$ gene. The homozygous absence of aspartic acid at position 57 of the HLA DQ ß-chain (nonAsp/nonAsp) confers an approximately 100-fold relative risk for the development of type 1 diabetes. Those who are heterozygous with a single aspartic acid at position 57 (nonAsp/Asp) are far less likely to acquire diabetes and only marginally more susceptible than individuals who have aspartic acid on both DQ ß-chains, that is, homozygous Asp/Asp. Thus, the presence of aspartic acid at one or both alleles of DQ ß protects against the development of autoimmune diabetes. Indeed, the incidence of type 1 DM in any given population appears to be proportional to the gene frequency of nonAsp alleles in that population. In addition, arginine at position 52 of the DQ ß-chain confers marked susceptibility to type 1 DM. Position 57 of the DQ ß and position 52 of DQ ß are at critical locations of the HLA molecule that permit or prevent antigen presentation to T-cell receptors and activate the autoimmune cascade. However, type 1 DM seems unique among autoimmune diseases, in that, in addition to forming susceptibility, certain MHC haplotypes provide significant protection. The HLA-DRB1*0301, HLA-DRB1*0401, HLA-DQB1*0302, and HLA-DQA1*0301 alleles of MHC (IDDM1) confer high-risk susceptibility in humans, whereas other alleles such as HLA-DRB1*0403, HLA-DQB1*0602, and HLA-DQA1*0102 are negatively associated with type 1 DM and may confer resistance.

The observation that 20% of individuals from Europe or the United States carry protective HLA-DR2 haplotype, yet fewer than 1% of children with type 1 DM are

DR2 (DQB1*0602) positive, signifies the importance of genetics in disease development.

Type 1 DM represents a heterogeneous and polygenic disorder. About 20 non-HLA loci contributing to disease susceptibility have been identified. The function of only two non-HLA loci is known. IDDM2 on chromosome 11p5.5 is a polymorphic region that maps to a variable number of tandem minisatellite repeats (VNTR), with short class I VNTR alleles predisposing to type 1 DM and the longer class III alleles providing dominant protective effect. This locus contributes about 10% toward disease susceptibility. Another locus associated with type 1 DM in some populations is IDDM12 on chromosome 2q33, which maps close to two T-cell markers involved in the T-cell activation: cytotoxic T lymphocyte–associated protein4 (CTLA-4) and CD28. Studies in Italian and Spanish families have shown that a polymorphism at CTL4 gene (A-G transition at position 49 of exon 1) called G allele, is preferentially transmitted to the affected siblings.

Factors other than pure inheritance of HLA markers or other genes must also be involved in producing diabetes. For example, HLA-DR3 or -DR4 is found in approximately 50% of the general population, and (nonAsp/nonAsp) is found in approximately 20% of nondiabetic whites in the United States, yet the risk for type 1 DM in these subjects is only one tenth of that in an HLA identical sibling of an index case possessing these markers. Even siblings sharing only one haplotype have a 6–10-fold greater risk of development of type 1 DM compared with the normal population. In addition, about 10% of patients with type 1 DM do not possess either HLA-DR3 or -DR4, although most white diabetic patients lack at least one aspartic acid at position 57 of the DQ ß chain. The concordance rate among identical twins of whom one has type 1 DM is only 30–50%, suggesting the participation of environmental triggering factors or other genetic factors such as the postnatal selection of certain autoreactive T-cell clones that bear receptors recognizing “self.” This postnatal process occurs within the thymus and implies that identical twins are not identical with respect to the T-cell receptor repertoire they possess.

Type 1 DM among African Americans is associated with the same HLA genes as it is in whites. If a sibling shares both HLA-D haplotypes with an index case, the risk for type 1 DM in that individual is 12–20%; for a sibling sharing one haplotype, the risk is 5–7%; with no haplotypes in common, the risk is only 1–2%. It can be assumed that in whites, the overall risks to siblings is approximately 6% if the proband is younger than 10 yr of age and 3% if the proband is older at the time of diagnosis. The risk to offspring of a diabetic parent is 2–5%, with the higher risk occurring in the offspring of a diabetic father. In African Americans, these risks are only one half to two thirds of those in whites.

ENVIRONMENT.

Factors such as infections, chemicals, seasonality, and geographic locations have been suspected of contributing to differences in the incidence and prevalence of type 1 DM in various ethnic populations. No dominant environmental agent or agents responsible for triggering type 1 DM have been uncovered. Environmental risk determinants that have been vigorously investigated can be classified into viral infections, early infant diet, and chemicals.

Viral Infections and Vaccinations. Although the etiologic role of viral infections in human type 1 DM is controversial, coxsackie B3, coxsackie B4, cytomegalovirus, rubella, and mumps can infect human ß cells. Only congenital rubella infection is associated with diabetes in later life. It is estimated that 10–12% of patients infected with congenital rubella develop type 1 DM and that up to 40% develop impaired glucose tolerance. The diabetes induced by rubella resembles type 1 DM because it is associated to HLA-DR3 and/or HLA-DR4 and is mediated by immune responses against ß-cell antigens. There has been no convincing correlation between timing of childhood vaccinations and risk of type 1 DM.

Seasonal Factors. Seasonal and long-term cyclic variations occur in the incidence of IDDM. Newly recognized cases appear with greater frequency in the autumn and winter months in the northern and southern hemispheres. Seasonal variations are most apparent in the adolescent years. Attempts to link a pattern of long-term cyclicity with the incidence of mumps or other viral infections have not been successful.

Dietary Factors. Feeding cow's milk to animal models of type 1 DM has been associated with the development of diabetes in these animals. The likely mechanism is the molecular mimicry between a 17-amino acid peptide of the bovine serum albumin and the islet antigen 69. Even though there appears to be a strong relationship between cow's milk consumption and national incidence of diabetes in children, the role of cow's milk in human type 1 DM is controversial. N-nitroso compounds, derived from the conversion of nitrates from dietary vegetables and meat in the gut, have also been involved in the development of diabetes. The role of these compounds as a significant risk factor in the pathogenesis of diabetes remains controversial.

Chemicals. Drugs such as alloxan, streptozotocin (STZ), pentamidine, and Vacor are directly cytotoxic to ß cells and cause diabetes in experimental animals and humans. In susceptible animals, multiple subdiabetogenic doses of STZ induce primary ß-cell damage and subsequently immune responses against ß cells, providing mechanistic evidence that a ß-cell insult can elicit specific autoimmunity. Autoimmunity against ß cells has also been reported in humans after intoxication with the human rodenticide Vacor.

Figure 583–2 summarizes current concepts of the etiology of type 1 DM as an autoimmune disease, with a genetic component inherited through the HLA system, in which autoimmune destruction of ß cells is triggered by an as yet unidentified agent. The slope of decline in insulin varies, and the point at which clinical features appear corresponds to an approximately 80% destruction of the insulin secretory reserve. This process may take months to years, usually in adolescent and older patients, and weeks in the very young patient. Higher titers of spontaneous autoinsulin antibodies and islet cell antibodies are characteristic of the more active islet cell destruction typically seen in the younger patient and may prove useful in predicting evolving diabetes.

Environmental agents may serve as modifiers of disease pathogenesis rather than triggers. These include infectious agents, dietary factors, environmental toxins as well as other influencing variables such as sanitation, health care access, and vaccinations. Multiple infections during the 1st yr of life are associated with a decreased risk of type 1 DM. Increased risk has been associated with perinatal infections coupled with a protective effect of preschool daycare with a possible link to

the age-dependent modifying effect of infections on the developing immune system. Environmental exposures could act to promote and attenuate disease during different stages of development, with effect dependent on both timing and quantity of encounters.

Pathogenesis

AUTOIMMUNE INJURY.

Genetic predisposition and environmental factors lead to initiation of an autoimmune process against the pancreatic islets. It is also assumed that the autoimmune response needs to be sustained and diversified against multiple target proteins (epitope spreading) for prolonged periods of time to overcome protective mechanisms. The autoimmune attack on the pancreatic islets leads to a gradual and progressive destruction of ß cells with loss of insulin secretion. It is estimated that, at the onset of clinical diabetes, 80–90% of the pancreatic islets are destroyed. Regeneration of new islets has

Figure 583.2-2 Proposed model of the pathogenesis and natural history of type 1 DM. IVGTT = intravenous glucose tolerance test; GADA = glutamic acid decarboxylase antibody; IAA = insulin autoantibodies; ICA = islet cell antibody. (Adapted from Atkinson MA, Eisenbarth GS: Type 1 diabetes: New perspectives on disease pathogenesis and treatment. *Lancet* 2001; 358:221–9.)

been detected at onset of type 1 DM, and it is thought to be responsible for the honeymoon phase (a transient decrease in insulin requirement associated with improved ß-cell function). In young diabetic children, especially those of DR3/DR4 haplotypes, the destruction of ß cells is almost complete during the first 3 yr after the onset of hyperglycemia, whereas in older patients the ß-cell destruction may take up to 10 yr. These observations indicate that the impairment of ß-cell function at the onset of hyperglycemia is the consequence of both ß-cell destruction and cytokine-mediated inhibition of insulin secretion. The distinction between ß-cell destruction and inhibition of insulin secretion is important, since a fraction of ß-cells may be recovered providing that effective therapeutic interventions can be implemented at the onset of the disease. Once islet cell autoimmunity has begun, progression to islet cell destruction is quite variable, with some patients rapidly progressing to clinical diabetes while others remain in a nonprogressive state. Antigenic/epitope spreading of the autoantibody responses is an important marker of impending progression; those with but a single autoantibody progress slowly, whereas those with autoantibodies to multiple antigens most often progress rapidly. Most individuals progressing to overt diabetes express multiple anti-islet antibodies (GAD65, ICA512/IA-2, and IAA) by the time of diabetes onset. The autoimmune response against the pancreatic ß cells is believed to consist of four phases: (1) environmental insult, (2) priming of T cells, (3) T-cell differentiation, and (4) ß-cell destruction (Fig. 583–3).

Environment. Pathogens can initiate or precipitate the self-reactive process by three possible mechanisms. First, molecular mimicry between viral proteins and self-proteins expressed by ß cells (i.e., PC2 protein of coxsackie virus and GAD65, rubella virus capsid protein and 52-kd islet protein, cytomegalovirus and 38-kd islet protein). Second, after acute ß-cell infection or ß-cell damage induced by cytokines during inflammatory responses against pathogens, the released proteins can be taken up by antigen presenting cells (APCs), which present the self-peptides to T cells. Third, cytokines secreted during a viral infection can upregulate the expression of co-stimulatory and MHC molecules on the surface of the facultative or nonfacultative APCs, enabling them to present self-peptides in immunogenic form to T cells. Exposure to microbial and viral pathogens early in life may also be protective against the development of type 1 DM.

Priming of T Cells. The presentation of ß cell–specific autoantigens by APC macrophages or dendritic cells [DCs]) to CD4 T helper (Th) cells in association with MHC class II molecules is considered the first step in the initiation of disease process (see Fig. 583–3). Macrophages secrete interleukin (IL)-12, stimulating CD4 T cells to secret interferon-? and IL-2. Interferon-? stimulates other resting macrophages to release, in turn, other cytokines such as IL-1ß, tumor necrosis factor (TNF)-a, and free radicals (NO, O^-_2), which are toxic to pancreatic ß cells. During this process, cytokines induce the migration of ß-cell autoantigen-specific CD8 cytotoxic cells. On recognizing specific autoantigens on ß cells in association with class 1 molecule, these CD8 cytotoxic T cells cause ß-cell damage by releasing perforin and granzyme and by Fas-mediated apoptosis of the ß cells.

Differentiation of T Cells. Immune-mediated diabetes is associated with polyclonal populations of T cells reactive against multiple ß-cell antigens. Thus T cells reactive against specific glutamic acid decarboxylase 65 (GAD65), proinsulin, tyrosine phosphatase (ICA512/IA-2), heat shock protein 60 (hsp60), and islet antigen 69 (ICA69) have been detected in type 1 DM patients. Among these antigens, GAD65 appears to be the early target of T cells. Because GAD65 is an intracellular protein, ß-cell injury may be required to initiate the autoimmune process. The association between MHC class II and type 1 DM strongly suggests a pathogenic role of CD4 T cells, because MHC class II molecules are required for thymic education of precursors and for the restriction of CD4 T-cell responses. There is a correlation between the binding affinity of the peptide to MHC class II and antigenicity. Whereas the type 1 DM protective class II molecules bind self-peptides with high affinity and delete thymic precursors, type 1 DM–susceptible class II molecules bind self-peptides with low affinity, leading to a failure of central tolerance and escape of self-reactive T cells to periphery. T cells are differentiated into Th1 and Th2 effector cells. Th1 cells protect against intracellular microbes and parasites, and mediate delayed-type hypersensitivity and acute allograft rejection, whereas Th2 cells regulate humoral immune responses (IgE and IgG1), mediate allergic reactions, and protect against organ-specific autoimmune diseases such as type 1 DM, multiple sclerosis, thyroiditis, and Crohn disease. CD4 Th1 cells secrete IL-2 and interferon-? and are associated with cell-mediated immunity. Th2 cells secrete IL-4 and IL-10, and are associated with humoral and anti-inflammatory responses. A subset of regulatory T cells known as natural killer T (NKT) cells prevents diabetes by secretion of IL-4 and/or IL-10. The regulatory Th3 (CD4) cells also tend to exert antidiabetogenic effect by the secretion of the suppressive cytokine tumor growth factor-ß. Functional abnormalities in these regulatory cells may also play a role in the pathogenesis of type 1 DM.

Figure 583.2-3 Schematic representation of the autoimmune response against the pancreatic ß cells. An insult on the pancreas leads to the release of ß-cell antigens (GAD65), which are taken up by antigen-presenting cells (APCs) and the epitopes presented to the CD4 T cells. Type and stages of activation of APCs as well as the cytokine environment, in which the CD4 T cell priming takes place, dictate the differentiation of autoreactive T cells toward diabetogenic T helper-1 (Th1) cells, Th2 cells, or antigen-specific regulatory T cells. A predominant Th1 autoimmune response results in the recruitment and differentiation of cytotoxic CD8 cells, which attack the pancreatic ß cells, leading to a massive release of ß-cell antigens, epitope spreading, and destruction of the pancreatic islets. B, B cell; DC, dendritic cell; M, macrophage; CTL, cytotoxic cell; TGF-ß, tumor growth factor-ß; INF?, interferon-?; IL, interleukin. (Adapted from Casares S, Brumeanu TD: Insights into the pathogenesis of type 1 diabetes: A hint for novel immunospecific therapies. *Curr Molec Med* 2001;1:357–78.)

ß-Cell Destruction. Mononuclear cell infiltration into the pancreatic islets (insulitis) and a reduction of insulin-producing ß cells are recognized as key pathologic features of type 1 DM. Pancreatic biopsy samples obtained from prediabetic patients and from those with recent-onset type 1 DM have shown various degrees of reduction in ß-cell volume in all patients, yet insulitis could not be identified in about 50%. When insulitis is detected, the infiltrate is composed of CD8 and CD4 T cells, B cells, and macrophages, with a predominance of CD8 T cells. Inflamed islet cells show hyperexpression of MHC class I molecules. The degree of insulitis and hyperexpression of MHC class I molecules correlates with deteriorating glycemic control and GAD65 antibody levels. Fas is detected on ß cells within inflamed cells, whereas islet-infiltrating mononuclear cells express Fas ligand. An interaction between Fas on ß cells and Fas ligand on infiltrating cells might trigger selective apoptotic ß-cell death in inflamed cells, leading to type 1 DM.

Prediction and Prevention.

Autoimmunity precedes clinical type 1 DM, and indicators of maturing autoimmune responses may be useful markers for disease prediction. Individuals at risk for type 1 DM can be identified using a combination of genetic, immunologic, and metabolic markers. The most informative genetic locus, HLA class II, confers about half of the total genetic risk but has a low positive predictive value (PPV) when used in the general population. Autoantibodies provide a practical readout of ß-cell autoimmunity, are easily sampled in venous blood, and have become the mainstay of type 1 DM prediction efforts. Initially described in terms of the islet cell antibody (ICA) immunofluorescence assay on pancreatic sections, autoantibodies are described in terms of defined ICA target antigens, such as insulin (IAA), glutamic acid dehydrogenase (GAD65), and the tyrosine phosphatase homologue ICA512/IA-2.

Autoantibodies are useful for detecting developing type 1 DM in close relatives of diabetic patients whose risk for diabetes is about 3.5–5.0%. However, most cases are sporadic rather than familial, necessitating general population screening. This has been difficult, in part, because the observed autoantibody prevalence greatly exceeds the low disease prevalence in nonrelatives, leading to high false-positive rates. Single defined autoantibody (d-aab) positivity may result from persistent memory B cells in lymph nodes or bone marrow after brief transient insulitis not resulting in clinical diabetes. It has been suggested that because different d-aab appear sequentially over time during prediabetes, the presence of multiple d-aab may mark more persistent insulitis and greater diabetes risk. In the first-degree relatives of patients with type 1 DM, the number of positive d-aab can help estimate the risk of developing type 1 DM: low risk (single d-aab: PPV of 2–6%), moderate risk (2 d-aab: PPV of 21–40%), and high risk (>2 d-aab: PPV of 59%–80%) over a 5-yr period. In children carrying the type 1 DM highest-risk genotype (HLA-DQB1*0201-DQA1*05/DQB1*0302-DQA1*03), insulitis is almost 10 times more frequent (PPV 21%) than in children with other genotypes (PPV 2.2%). On the other hand, in general populations of children, some studies have suggested a very low overall PPV for single d-aab (0–0.5%), whereas overall PPV for multiple (=2) d-aab has been reported to be as high as 19–50% (high risk) over a 2–8 yr period.

There is no known agent capable of preventing type 1 DM. There are several obstacles to finding a plausible prevention

strategy. These include (1) ethical issues surrounding prediction, (2) treatment dilemma, (3) selection of populations at risk and treatment strategies, and (4) finding new preventive agents. The ability to predict future cases of type 1 DM, although a major benefit to knowledge about the natural history of this disease, in the absence of a preventing agent raises ethical considerations related to induction of stress, lifestyle changes, and potential effects on insurability.

A second challenge facing the diabetes prevention efforts is treatment dilemma. It is well recognized that the most effective interventions are those that are started early in the autoimmune process. However, the process of disease prediction, using immunologic, genetic, and metabolic markers, is most accurate in the period close to the onset of overt diabetes. Consequently, many health care providers and researchers are faced with ethical and clinical conflicts wherein the most effective forms of therapy might involve treatment of individuals in a period in which disease prediction is less accurate. Also, it has been very difficult to find safe and benign forms of therapy that can be used in individuals who may never develop type 1 DM.

Another obstacle is the selection of type of populations and appropriate therapeutic approaches. Attempts to prevent type 1 DM need to address therapy of high-risk population (relatives of type 1 DM patients with positive immune markers) versus the general population with low risk of developing diabetes. Whereas clinical trials in high-risk populations may be more efficient and cost-effective, the general population approach may be more important because about 85% of new cases of type 1 DM have no family history of the disease. In the general population, a safe and benign therapy capable of interrupting adverse immune events and environmental agents or alterations in lifestyle providing avoidance of disease risk factors would ideally be implemented. There is a considerable cost associated with screening general populations. Vitamin D supplementation of infants and maternal intake of cod liver oil during pregnancy have been shown to be associated with the reduced risk of type 1 DM in children. This protective effect of vitamin D is believed to be due to its immunosuppressive action, reducing lymphocyte proliferation and cytokine production. Therefore, age-appropriate vitamin D supplementation of all infants can

be a relatively inexpensive strategy in the general population.

Another issue is the lack of an obvious therapeutic agent for diabetes prevention. For instance, the United States Diabetes Prevention Trial I (DPT-I) was started in 1994 to determine whether antigen-based therapies with insulin (i.e., low-dose parenteral insulin therapy to high-risk relatives or oral insulin vs placebo to intermediate-risk relatives) would prevent or delay the onset of diabetes. Therapy did not provide evidence for disease prevention, and the 2-yr results of oral insulin and low-dose parenteral insulin will be released soon.

IMMUNOTHERAPY IN NEW-ONSET TYPE 1 DM.

Type 1 DM is a T-cell–mediated autoimmune disease that begins, in many cases, 3–5 yr before the onset of clinical symptoms, continues after diagnosis, and can recur after islet transplantation. The effector mechanisms responsible for the destruction of ß-cells involve cytotoxic T cells as well as soluble T-cell products, such as interferon-? and TNF-a. Such observations have led to clinical trials with immunomodulatory drugs such as cyclosporine, azathioprine, prednisone, and antithymocyte globulin, which were shown to cause transient improvement in clinical measures and to increase the rate of non–insulin-requiring remissions when initiated soon after diagnosis. Unfortunately, the toxic effects of such drugs, concern about the risk associated with immune suppression, and the need for continuous treatment in an otherwise healthy, young population limit the use of these agents.

Immunotherapy using modified monoclonal antibody against CD3 hOKT3?1 has efficacy in patients with renal-allograft rejection. Treatment with hOKT3?1 infusions mitigates the deterioration in insulin production and improves metabolic control during the 1st yr of type 1 DM in a majority of patients. The side effects include transient fever, gastrointestinal symptoms, and pruritic rash, without any long-term toxic effects up to 2 yr. The mechanisms of action of the anti-CD3 monoclonal antibody may involve direct effects on pathogenic T cells and/or the induction of populations of regulatory cells.

Pathophysiology.

Insulin performs a critical role in the storage and retrieval of cellular fuel. Its secretion in response to feeding is exquisitely modulated by the interplay of neural, hormonal, and substrate-related mechanisms to permit controlled disposition of ingested foodstuff as energy for immediate or future use. Insulin levels must be lowered to then mobilize stored energy during the fasted state. Thus, in normal metabolism, there are regular swings between the postprandial, high-insulin anabolic state and the fasted, low-insulin catabolic state that affect liver, muscle, and adipose tissue (Table 583–3). Type 1 DM is a progressive low-insulin catabolic state in which feeding does not reverse but rather exaggerates these catabolic processes. With moderate insulinopenia, glucose utilization by muscle and fat decreases and postprandial hyperglycemia appears. At even lower insulin levels, the liver produces excessive glucose via glycogenolysis and gluconeogenesis, and fasting hyperglycemia begins. Hyperglycemia produces an osmotic diuresis (glucosuria) when the renal threshold is exceeded (180?mg/dL; 10?mmol/L). The resulting loss of calories and electrolytes, as well as the persistent dehydration, produce a physiologic stress with hypersecretion of stress hormones (epinephrine, cortisol, growth hormone, and glucagon). These hormones, in turn, contribute to the metabolic decompensation by further impairing insulin secretion (epinephrine), by antagonizing its action (epinephrine, cortisol, growth hormone), and by promoting glycogenolysis, gluconeogenesis, lipolysis, and ketogenesis (glucagon, epinephrine, growth hormone, and cortisol) while decreasing glucose utilization and glucose clearance (epinephrine, growth hormone, cortisol).

The combination of insulin deficiency and elevated plasma values of the counter-regulatory hormones is also responsible for accelerated lipolysis and impaired lipid synthesis, with resulting increased plasma concentrations of total lipids, cholesterol, triglycerides, and free fatty acids. The hormonal interplay of insulin deficiency and glucagon excess shunts the free fatty acids into ketone body formation; the rate of formation of these ketone bodies, principally ß-hydroxybutyrate and acetoacetate, exceeds the capacity for peripheral utilization and renal excretion. Accumulation of these ketoacids results in

TABLE 583.2-3 -- Influence of Feeding (High Insulin) or of Fasting (Low Insulin) on Some Metabolic Processes in Liver, Muscle, and Adipose Tissue

	High Plasma Insulin (Postprandial State)	**Low Plasma Insulin (Fasted State)**
Liver	Glucose uptake	Glucose production
	Glycogen synthesis	Glycogenolysis
	Absence of gluconeogenesis	Gluconeogenesis
	Lipogenesis	Absence of lipogenesis
	Absence of ketogenesis	Ketogenesis
Muscle	Glucose uptake	Absence of glucose uptake
	Glucose oxidation	Fatty acid and ketone oxidation
	Glycogen synthesis	Glycogenolysis
	Protein synthesis	Proteolysis and amino acid release

Adipose tissue	Glucose uptake	Absence of glucose uptake
	Lipid synthesis	Lipolysis and fatty acid release
	Triglyceride uptake	Absence of triglyceride uptake

** Insulin is considered to be the major factor governing these metabolic processes. Diabetes mellitus may be viewed as a permanent low-insulin state that, untreated, results in exaggerated fasting.*

metabolic acidosis (diabetic ketoacidosis, DKA) and compensatory rapid deep breathing in an attempt to excrete excess CO_2 (Kussmaul respiration). Acetone, formed by nonenzymatic conversion of acetoacetate, is responsible for the characteristic fruity odor of the breath. Ketones are excreted in the urine in association with cations and thus further increase losses of water and electrolyte. With progressive dehydration, acidosis, hyperosmolality, and diminished cerebral oxygen utilization, consciousness becomes impaired, and the patient ultimately becomes comatose.

Clinical Manifestations.

As diabetes develops, symptoms steadily increase, reflecting the decreasing ß-cell mass, worsening insulinopenia, progressive hyperglycemia, and eventual ketoacidosis. Initially, when only insulin reserve is limited, occasional hyperglycemia occurs. When the serum glucose increases above the renal threshold, intermittent polyuria or nocturia begins. With further ß-cell loss, chronic hyperglycemia causes a more persistent diuresis, often with nocturnal enuresis; polydipsia becomes more apparent. Female patients may develop monilial vaginitis due to the chronic glucosuria. Calories are lost in the urine (glucosuria), triggering a compensatory hyperphagia. If this hyperphagia does not keep pace with the glucosuria, loss of body fat ensues, with clinical weight loss and diminished subcutaneous fat stores. An average healthy 10-yr-old child consumes about 50% of 2,000 daily calories as carbohydrate. As that child becomes diabetic, daily losses of water and glucose may be 5?L and 250?g, respectively, representing 1,000 calories, or 50%, of the average daily caloric intake. Despite the child's compensatory increased intake of food, the body starves, because unused calories are lost in the urine.

When extremely low insulin levels are reached, ketoacids accumulate. At this point, the child quickly deteriorates. Ketoacids produce abdominal discomfort, nausea, and emesis, preventing oral replacement of urinary water losses. Dehydration accelerates, causing weakness or orthostasis—but polyuria persists. As in any hyperosmotic state, the degree of dehydration may be clinically underestimated because intravascular volume is conserved at the expense of intracellular volume. Ketoacidosis exacerbates prior symptoms and leads to Kussmaul respirations (deep heavy rapid breathing), fruity breath odor (acetone), diminished neurocognitive function, and possible coma. About 20–40% of children with new-onset diabetes progress to DKA before diagnosis.

This entire progression happens much more quickly (over a few weeks) in younger children, probably due to a more aggressive autoimmune destruction of ß cells. In infants, most of the weight loss is acute water loss, because they will not have had a prolonged caloriuria when diagnosed, and there will be an increased incidence of DKA at diagnosis. In adolescents, the course is usually more prolonged (over months), and most of the weight loss represents fat loss due to prolonged starvation. Additional weight loss due to acute dehydration may occur just before diagnosis. In any child, the progression of symptoms may be accelerated by the stress of an intercurrent illness or trauma, when counter-regulatory (stress) hormones overwhelm the limited insulin secretory capacity.

Diagnosis.

The diagnosis of type 1 diabetes is usually straightforward *if considered in the differential diagnosis*. Although most symptoms are nonspecific, the most important clue is an inappropriate polyuria in any child with dehydration, poor weight gain, or “the flu.” Hyperglycemia, glucosuria, and ketonuria can be determined quickly. Nonfasting blood glucose greater than 200?mg/dL (11.1?mmol/L) with typical symptoms is diagnostic with or without ketonuria. In the obese child, type 2 diabetes must be considered (see later text). Once hyperglycemia is confirmed, it is prudent to determine whether DKA is present (especially if ketonuria is found) and to evaluate electrolyte abnormalities—even if signs of dehydration are minimal. A baseline glycohemoglobin (HbA_{1c}) allows an estimate of the duration of hyperglycemia and provides an initial value by which to compare the effectiveness of subsequent therapy.

In the nonobese child, testing for autoimmunity to ß cells is not necessary. Other autoimmunities associated with type 1 diabetes should be screened, including celiac disease (tissue transglutaminase IgA and total IgA) and thyroiditis (antithyroid peroxidase and antithyroglobulin antibodies). Because significant physiologic distress can disrupt the pituitary-thyroid axis, a free thyroxine (T_4) and TSH should be checked after the child is stable for a few weeks.

Rarely, a child has transient hyperglycemia with glucosuria while under substantial physical stress. This usually resolves permanently during recovery from the stressors. However, such stress hyperglycemia could reflect a limited insulin reserve temporarily revealed by counter-regulatory hormones. A child with temporary hyperglycemia should therefore be monitored for the development of symptoms of persistent hyperglycemia and tested if such symptoms occur. Formal testing in a child who remains clinically asymptomatic is not necessary.

Routine screening procedures, such as postprandial determinations of blood glucose or screening oral glucose tolerance tests, have yielded low detection rates in healthy, asymptomatic children, even among those considered at risk, such as siblings of diabetic children. Accordingly, such screening procedures are not recommended in children.

DIABETIC KETOACIDOSIS.

DKA is the end result of the metabolic abnormalities resulting from a severe deficiency of insulin or insulin effectiveness. The latter occurs during stress as counter-regulatory hormones block insulin action. DKA occurs in 20–40% of children with new-onset diabetes, and in children with known diabetes who omit insulin doses or who do not successfully manage an intercurrent illness. DKA may be arbitrarily classified as mild, moderate, or severe (Table 583–4), and the range of symptoms depends on the depth of ketoacidosis. There is a large ketonuria, an increased ion gap, a decreased serum bicarbonate (or total CO_2) and pH, and an elevated effective serum osmolality indicating hypertonic dehydration.

Treatment.

Therapy is tailored to the degree of insulinopenia at presentation. Most children with new diabetes (60–80%) have mild to moderate symptoms, minimal dehydration with no history of emesis, and have not progressed to ketoacidosis. Once DKA has resolved in the newly diagnosed child, therapy is transitioned to that described for children with nonketotic onset. Children with previously diagnosed diabetes who develop DKA are usually transitioned to their previous insulin regimen.

NEW ONSET DIABETES WITHOUT KETOACIDOSIS.

Excellent diabetes control involves many goals: to maintain a balance between tight glucose control and avoiding hypoglycemia, to eliminate polyuria and nocturia, to prevent ketoacidosis, and to

TABLE 583.2-4 -- Classification of Diabetic Ketoacidosis

	Normal	**Mild**	**Moderate**	**Severe**[†]
CO_2 (mEq/L, venous)[*]	20–28	16–20	10–15	<10
pH (venous)[*]	7.35–7.45	7.25–7.35	7.15–7.25	< 7.15
Clinical	No change	Oriented, alert but fatigued	Kussmaul respirations; oriented but sleepy; arousable	Kussmaul or depressed respirations; sleepy to depressed sensorium to coma

† Severe hypernatremia (corrected Na > 150?mEq/L) would also be classified as severe DKA.
$^*CO_2$ and pH measurement are method dependent; normal ranges may vary.

permit normal growth and development with minimal effect on lifestyle. Therapy encompasses initiation and adjustment of insulin, extensive teaching of the child and caretakers, and reestablishing the routine of life. Each aspect should be addressed early in the overall care for the family. Ideally, therapy can begin in the outpatient setting, with complete team staffing by a pediatric endocrinologist, experienced nursing staff, dietitians with training as diabetes educators, and a social worker. Close contact between the diabetes team and family must be assured. Otherwise, initial therapy should be done in the hospital setting.

INSULIN.

Several factors influence the initial daily insulin dose per kilogram of body weight. The dose is usually higher in pubertal children. It is higher in those who have to restore greater deficits of body glycogen, protein, and fat stores and who, therefore, have higher initial caloric capacity. On the other hand, most children with new-onset diabetes have some residual ß-cell function (the “honeymoon” period), which reduces exogenous insulin needs. Children with longstanding diabetes and no insulin reserve require about 0.7 units/kg/d if prepubertal, 1.0 unit/kg/d at midpuberty, and 1.2 units/kg/d by the end of puberty. A reasonable dose in the newly diagnosed child, then, is about 60–70% of the full replacement dose based on pubertal status. The optimal insulin dose can only be determined empirically, with frequent self-monitored blood glucose levels and insulin adjustment by the diabetes team. Residual ß-cell function usually fades within a few months and is reflected as a steady increase in insulin requirements and wider glucose excursions.

The initial insulin *schedule* should be directed toward the optimal degree of glucose control in an attempt to duplicate the activity of the ß cell. There are inherent limits to our ability to mimic the ß cell. Exogenous insulin does not have a first pass to the liver, whereas 50% of pancreatic portal insulin is taken up by the liver, a key organ for the disposal of glucose; absorption of an exogenous dose continues despite hypoglycemia, whereas endogenous insulin release ceases and serum levels quickly lower with a normally rapid clearance; and absorption rate from an injection varies by injection site and patient activity level, whereas endogenous insulin is secreted directly into the portal circulation. Despite these fundamental physiologic differences, quite acceptable glucose control can be obtained with new insulin analogs used in a basal-bolus regimen, that is, with slow onset, long duration background insulin for between meal glucose control, and rapid-onset insulin at each meal.

All preanalog insulins form hexamers, which must dissociate into monomers subcutaneously before being absorbed into the circulation. Thus, a detectable effect for regular (R) insulin is delayed by 30–60?min after injection. This, in turn, requires delaying the meal 30–60?min after the injection for optimal effect—a delay rarely attained in a busy child's life. R has a wide peak and a long tail for bolus insulin (Figs. 583–4 and 583–5). This profile limits postprandial glucose control, produces prolonged peaks with excessive hypoglycemic effects between meals, and increases the risk of nighttime hypoglycemia. These unwanted between-meal effects often necessitate “feeding the insulin” with snacks and limiting the overall degree of blood glucose control. NPH and Lente insulins also have inherent limits because they do

not create a peakless background insulin level (see Fig. 583–4*C–E*). This produces significant hypoglycemic effect during the midrange of their duration. Thus, it is often difficult to predict their interaction with fast-acting insulins. When R is combined with NPH or lente (see Fig. 583–4*E*), the composite insulin profile poorly mimics normal endogenous insulin secretion. There are broad areas of excessive insulin effect alternating with insufficient effect throughout the day and night.

Lispro (L) and aspart (A), insulin analogs, are absorbed much quicker because they do not form hexamers. They provide discrete pulses with little if any overlap and short tail effect. This allows better control of postmeal glucose increase and reduces between meal or nighttime hypoglycemia (Fig. 583–4*A*). The long-acting analog glargine (G) creates a much flatter 24-hr profile, making it easier to predict the combined effect of a rapid bolus (L or A) on top of the basal insulin, producing a more physiologic pattern of insulin effect (see Fig. 583–4*A*). Postprandial glucose elevations are better controlled, and between meal and nighttime hypoglycemia are reduced.

Ultralente (UL) given twice a day can provide a reasonable basal profile (see Fig. 583–5*C*) and is quite effective when used with lispro or aspart (see Fig. 583–4*B*). This combination may be used in children for whom glargine does not produce a complete 24-hr basal coverage.

The basal insulin glargine should be 25–30% of the total dose in toddlers and 40–50% in older children. The remaining portion of the total daily dose is divided evenly as bolus injections for the three meals. A simple three- or four-step dosing schedule is begun based on the blood glucose level (Table 583–5). As soon as the family is taught to calculate the carbohydrate content of meals, bolus insulin can be more accurately dosed by both the carbohydrate content of the meal as well as ambient glucose (see Table 583–5).

Frequent blood glucose monitoring and insulin adjustment are necessary in the first weeks as the child returns to routine activities and adapts to a new nutritional schedule, and as the total daily insulin requirements are determined. The major physiologic limit to tight control is hypoglycemia. Intensive control dramatically reduces the risk of long-term vascular complications; it is associated with a three-fold increase in severe hypoglycemia. Use of insulin analogs moderates but does not eliminate this problem.

Some families may be unable to administer four daily injections. In these cases, a compromise may be needed. A three-injection regimen combining the basal insulin ultralente (at breakfast and supper) with a rapid analog bolus at each meal may provide good glucose control. Further compromise to a two-injection regimen may occasionally be needed. This would require NPH or lente combined with a rapid analog bolus at breakfast and supper. However, such a schedule would provide poor coverage for lunch and early morning, and would increase the risk of hypoglycemia at midmorning and early night.

INSULIN PUMP THERAPY.

Continuous subcutaneous insulin infusion (CSII) via battery-powered pumps provides a closer approximation of normal plasma insulin profiles and increased flexibility regarding timing of meals and snacks compared to conventional insulin injection regimens. Insulin pump therapy in adolescents with type 1 DM is associated with improved metabolic control and reduced risk of severe hypoglycemia without affecting psychosocial outcomes. The use of overnight CSII improves the metabolic control in children ages 7–10 yr. CSII has also been useful in toddlers. Others have demonstrated that CSII was associated with improved metabolic control in only 39% of patients and that the remainder of the patients either did not show reduction in HbA_{1c} (41%) or showed deterioration in metabolic control (20%). These investigators reported a mean HbA_{1c} of 8.3%, which is similar to that reported by the Diabetes Control and Complications Trial (DCCT) adolescents of 8.1%. The degree of glycemic control is mainly dependent on how closely patients adhere to the principles of diabetes self-care, regardless of the type of intensive insulin regimen. A greater proportion of patients on insulin pump therapy experience decreased seizure and hypoglycemic frequency as well as severe hypoglycemic episodes. CSII therapy is not associated with an abnormal increase in body weight.

INHALED AND ORAL INSULIN THERAPIES.

Preprandial inhaled insulin is being evaluated in adults with type 1 and type 2 DM. The preliminary metabolic data is promising. Patients on premeal inhaled insulin in combination with once daily bedtime long-acting insulin (ultralente) injection achieved similar

Figure 583.2-4 Approximate composite insulin effect profiles. Meals are shown as rectangles below time axis. Injections are shown as labeled triangles. L/A = lispro or aspart. Even though the fast and long-acting insulins are shaded differently to show the addition of one insulin effect to another, the profile is changed to show the combined effect. For example, in the breakfast injection in C, the quick decline of L/A effect is blunted by the rising NPH/lente effect, producing a broad tail, which slowly declines to baseline at supper. All profiles are idealized using average absorption and clearance rates. In typical clinical situations, these profiles vary among patients. A given patient has varying rates of absorption depending on the injection site, physical activity, and other variables. *A,* L or A pre-meal; glargine at bedtime. The rapid onset and short duration of L or A reduce overlap between pre-meal injections, and there is no extended nighttime action. This reduces the risk of hypoglycemia. Glargine provides a steady basal profile that simplifies prediction of bolus insulin effect. *B,* L or A pre-meal; ultralente at breakfast and supper. Ultralente produces a basal profile similar to that seen with glargine. Some excessive insulin effect, however, is seen before supper and at nighttime. *C,* L or A pre-meal; NPH or lente at breakfast and supper. The broad peak of NPH or lente produces substantial risk of hypoglycemia before lunch and during the early hours of the night. The waning insulin effect before supper and breakfast may also allow breakthrough hyperglycemia. *D,* L or A pre-meal; NPH or lente at breakfast and bedtime. Moving the evening long-acting insulin helps to cover the pre-breakfast hours, but the risk of nighttime lows persists. *E,* Regular and NPH or lente at breakfast and supper. This produces the least physiologic profile, with large excesses before lunch and during the early night, combined with poor coverage before supper and breakfast.

Figure 583.2-5 Approximate insulin effect profiles. *A,* The following relative peak effect and duration units are used: lispro/aspart, peak 20 for 4 hours; regular, peak 15 for 7 hours; NPH/lente, peak 12 for 12 hours; ultralente, peak 9 for 18 hours; glargine, peak 5 for 24 hours. ?,Injection time. *B,* Two ultralente injections given at breakfast and supper. Note overlap of profiles. *C,* Composite curve showing approximate cumulative insulin effect for the two ultralente injections. This composite view is much more useful to the patient, parents, and medical personnel because it shows important combined effects of multiple insulin injections with variable absorption characteristics and overlapping durations.

metabolic control compared to patients on two to three daily injections of insulin. There was no significant difference in the frequency of hypoglycemic episodes between the two groups. There have been reports of pulmonary fibrosis in a small number of patients, necessitating further monitoring and evaluation of patients on inhaled insulin before this route of insulin administration is deemed safe.

Premeal oral insulin (Oralin) has been evaluated in comparison with oral hypoglycemic agents, mostly in patients with type 2 DM. The clinical data appears promising, but further evaluation of its efficacy in type 1 DM is needed.

BASIC EDUCATION.

Therapy consists not only of initiation and adjustment of insulin dose but also of education of the patient and family. Teaching is most efficiently provided by experienced diabetes educators and nutritionists. In the acute phase, the family must learn the "basics," which includes monitoring the child's blood glucose and urine ketones, preparing and injecting the correct insulin dose subcutaneously at the proper time, recognizing and treating low blood glucose reactions, and having a basic meal plan. Most families trying to adjust psychologically to the new diagnosis of diabetes in their child consequently have a limited ability to retain new information. Written materials covering these basic topics help the family during the first few days.

KETOACIDOSIS.

Severe insulinopenia (or lack of effective insulin action) results in a physiologic cascade of events in three general pathways.

1. Excessive glucose production coupled with reduced glucose utilization raises serum glucose. This produces an osmotic diuresis, with loss of fluid and electrolytes, dehydration, and activation of the renin-angiotensin-aldosterone axis with accelerated potassium loss. If glucose elevation and dehydration are severe and persist for several hours, the risk of cerebral edema increases.
2. Increased catabolic processes result in cellular losses of sodium, potassium, and phosphate.
3. Increased release of free fatty acids from peripheral fat stores supplies substrate for hepatic ketoacid production. When ketoacids accumulate, buffer systems are depleted and a metabolic acidosis ensues. Therapy must address both the initiating event in this cascade (insulinopenia) and the subsequent physiologic disruptions.

Reversal of DKA is associated with inherent risks that include hypoglycemia, hypokalemia, and cerebral edema. Any protocol must be used with caution and close monitoring of the patient. Adjustments based on sound medical judgment may be necessary for any given level of DKA (Table 583–6).

HYPERGLYCEMIA AND DEHYDRATION.

Insulin must be given at the beginning of therapy to accelerate movement of glucose into cells, to subdue hepatic glucose production, and to halt the movement of fatty acids from the periphery to the liver. However, an initial insulin bolus does not speed recovery and may increase the risk of hypokalemia and hypoglycemia. Therefore, insulin infusion is begun without a bolus at a rate of 0.1 unit/kg/h. This approximates maximal insulin output in normal subjects during an oral glucose tolerance test. Rehydration also lowers glucose levels by improving renal perfusion and enhancing renal excretion. The combination of these therapies usually causes a rapid initial decline in serum glucose levels. Once glucose goes below 180?mg/dL (10?mmol/L), the osmotic diuresis stops and rehydration accelerates without further increase in the infusion rate.

Repair of hyperglycemia occurs well before correction of acidosis. Therefore, insulin is still needed to control fatty acid release after normal glucose levels are reached. To continue the

TABLE 583.2-5 -- Subcutaneous Insulin Dosing

Age (years)	Target Glucose (mg/dL)	Total Daily Insulin (units/kg/d)*	Basal Insulin, % of Total Daily Dose	Bolus† Insulin	
				Units Added per 100?mg/dL above Target	***Units Added Per 15?g at Meal***
0–5	100–200	0.6–0.7	25–30	0.50	0.50
5–12	80–150	0.7–1.0	40–50	0.75	0.75
12–18	80–150	1.0–1.2	40–50	1.0–2.0‡	1.0–2.0

**Newly diagnosed children in the "honeymoon" may only need 60–70% of a full replacement dose. Total daily dose per kg increases with puberty.*
† Newly diagnosed children who do not use carbohydrate dosing should divide the nonbasal portion of the daily insulin dose into equal doses for each meal. A dosing scale is then added for each dose. ***For example:*** *a 6-yr-old child who weighs 20?kg needs about (0.7 units/kg/24?hr × 20?kg) = 14 units/24?hr with 7 units (50%) as basal and 7 units as total daily bolus. Give basal as glargine at hs. Give 2 units lispro or aspart before each meal if the blood glucose is within target; subtract 1 unit if below target; add 0.75 unit for each 100?mg/dL above target (round the dose to the nearest 0.5 unit).*
‡ For more finessed control, extra insulin may be added for 50-mg/dL increments.

TABLE 583.2-6 -- **Diabetic Ketoacidosis Treatment Protocol**

Time	Therapy	Comments
1st hour	10–20?mL/kg IV bolus 0.9% NaCl or LR Insulin drip at 0.05 to 0.10?u/kg/hr	Quick volume expansion; may be repeated. NPO. Monitor I/O, neurologic status. Use flow sheet. Have mannitol at bedside; 1?g/kg IV push for cerebral edema.
2nd hour until DKA resolution	0.45 % NaCl: plus continue insulin drip 20?mEq/L KPhos and 20?mEq/L KAc 5% glucose if blood sugar <250?mg/dL (14?mmol/L)	If K <3?mEq/L, give 0.5 to 1.0?mEq/kg as oral K solution *OR* increase IV K to 80?mEq/L
Variable	Oral intake with subcutaneous insulin	No emesis; CO_2 = 16?mEq/L; normal electrolytes
Note that the initial IV bolus is considered part of the total fluid allowed in the first 24?hr and is subtracted before calculating the IV rate.		
Maintenance (24?hr) = 100?mL/kg (for the 1st 10?kg) + 50?mL/kg (for the 2nd 10?kg) + 25?mL/kg (for all remaining kg)		
Sample calculation for a 30-kg child:		
1st hour = 300?mL IV bolus 0.9% NaCl or LR		
NaCl, sodium chloride; LR, lactated Ringer solution; KPhos, potassium phosphate; KAc, potassium acetate; I/O, input and output (urine, emesis).		

insulin infusion without causing hypoglycemia, glucose must be added to the infusion, usually as 5% solution. Glucose should be added when the serum glucose has decreased to about 250?mg/dL (14?mmol/L) so that there is sufficient time to adjust the infusion before the serum glucose falls further. The insulin infusion can also be lowered from the initial maximal rate once hyperglycemia has resolved.

Repair of fluid deficits must be tempered by the potential risk of cerebral edema. It is prudent to approach any child in any hyperosmotic state with cautious rehydration. The effective serum osmolality (E_{osm} = 2 × [$Na_{uncorrected}$] + [glucose]) is an accurate index of tonicity of the body fluids, reflecting intracellular and extracellular hydration better than measured plasma osmolality. It is calculated with sodium and glucose in mmol/L. This value is usually elevated at the beginning of therapy and should steadily normalize. A rapid decline, or a slow decline to a subnormal range, may indicate an excess of free water entering the vascular space and an increasing risk of cerebral edema. Therefore, patients should not be allowed oral fluids until rehydration is well progressed and significant electrolyte shifts are no longer likely. Limited ice chips may be given as a minimal oral intake. All fluid intake and output should be closely monitored.

Calculation of fluid deficits using clinical signs is difficult in children with DKA because intravascular volume is better maintained in the hypertonic state. For any degree of tachycardia, delayed capillary refill, decreased skin temperature, or orthostatic blood pressure change, the child with DKA will be more dehydrated than the child with a normotonic fluid deficit. The protocol in Table 583–6 corrects a deficit of 85?mL/kg (8.5% dehydration) for all patients in the first 24?hr. Children with mild DKA rehydrate earlier and can be switched to oral intake, whereas those with severe DKA and a greater volume deficit require 30–36?hr with this protocol. This more gradual rehydration of the child with severe DKA is an inherent safety feature. The initial intravenous bolus (20?mL/kg of glucose-free isotonic sodium salt solution such as Ringer lactate or 0.9% sodium chloride) for all patients ensures a quick volume expansion and may be repeated if clinical improvement is not quickly seen. This bolus is given as isotonic saline because the patient is inevitably hypertonic, keeping most of the initial infusion in the intravascular space. Subsequent fluid is hypotonic to repair the free water deficit, to allow intracellular rehydration, and to allow a more appropriate replacement of ongoing hypotonic urine losses.

The initial serum sodium is usually normal or low because of the osmolar dilution of hyperglycemia and the effect of an elevated sodium-free lipid fraction. An estimate of the reconstituted, or “true,” serum sodium for any given glucose level above 100?mg/dL (5.6?mmol/L) is calculated as follows:

where glucose is in mg/dL, or

where glucose is in mmol/L.

One should expect the sodium to increase about 1.6?mmol/L for each 100?mg/dL decline in the glucose. The corrected sodium is usually normal or slightly elevated and indicates a moderate hypernatremic dehydration. If the corrected value is greater than 150?mmol/L, severe hypernatremic dehydration may be present and may require slower fluid replacement. The sodium should steadily increase with therapy. Declining sodium may indicate excessive free water accumulation and a risk of cerebral edema.

CATABOLIC LOSSES.

Both the metabolic shift to a catabolic predominance and the acidosis move potassium and phosphate from the cell to the serum. The osmotic diuresis, the kaliuretic effect of the hyperaldosteronism, and the ketonuria then accelerate renal losses of potassium and phosphate. Sodium is also lost with the diuresis, but free water losses are greater than isotonic losses. With prolonged illness and severe DKA, total body losses can approach 10–13?mEq/kg of sodium, 5–6?mEq/kg of potassium, and 4–5?mEq/kg of phosphate. These losses continue for several hours during therapy until the catabolic state is reversed and the diuresis is controlled. For example, 50% of infused sodium may be lost in the urine during IV therapy. Even though the sodium deficit may be repaired within 24?hr, intracellular potassium and phosphate may not be completely restored for several days.

Although patients with DKA have a total body potassium deficit, the initial serum level is often normal or slightly elevated. This is due to the movement of potassium from the intracellular space to the serum, both as part of the ketoacid buffering process and as part of the catabolic shift. These effects are reversed with therapy and potassium returns to the cell. (Note that therapy for hyperkalemia uses insulin and glucose in the same manner, i.e., to promote the anabolic movement of potassium into the cell.) Improved hydration increases renal blood flow, allowing for increased excretion of potassium in the elevated aldosterone state. The net effect is often a dramatic decline in serum potassium levels, especially in severe DKA, and can precipitate changes in cardiac conductivity, flattening of T waves, prolongation of the QRS complex, and cause skeletal muscle weakness or an ileus. The risk of myocardial dysfunction is increased with shock and acidosis. Potassium levels must be closely followed and electrocardiographic monitoring continued until DKA is substantially resolved. If needed, the parenteral

potassium can be increased to 80?mEq/L or an oral supplement can be given if there is no emesis. Rarely, the IV insulin must be temporarily stopped.

It is unclear whether phosphate deficits contribute to symptoms of DKA such as generalized muscle weakness. In pediatric patients, a deficit has not been shown to compromise oxygen delivery via a deficiency of 2,3-diphosphoglycerate (2,3-DPG). Because the patient will receive an excess of chloride, which may aggravate acidosis, it is prudent to use potassium phosphate rather than potassium chloride as a potassium source. Potassium acetate is also used, because it provides an additional source of metabolic buffer.

Pancreatitis is occasionally seen with DKA, especially if prolonged abdominal distress is present; serum amylase may be elevated. If, however, the serum lipase is not elevated, the amylase is likely nonspecific or salivary in origin. Serum creatinine adjusted for age may be falsely elevated due to interference by ketones in the autoanalyzer methodology. An initial elevated value rarely indicates renal failure and should be rechecked when the child is less ketonemic. Blood urea nitrogen (BUN) may be elevated with prerenal azotemia and should be rechecked as the child is rehydrated. Mildly elevated creatine or BUN is not reason to withhold potassium therapy if good urinary output is present.

KETOACID ACCUMULATION.

Low insulin infusion rates (0.02–0.05 units/kg/h) are sufficient to stop peripheral release of fatty acids, thus eliminating the flow of substrate for ketogenesis. Therefore, the initial infusion rate may be decreased if blood glucose levels go below 150?mg/dL (8?mmol/L) despite the addition of glucose to the infusion. Ketogenesis continues until fatty acid substrates already in the liver are depleted, but this production declines much more quickly without new substrate inflow. Bicarbonate buffers, regenerated by the distal renal tubule and by metabolism of ketone bodies, steadily repair the acidosis once ketoacid production is controlled. Bicarbonate therapy is rarely necessary and may even increase the risk of hypokalemia and cerebral edema.

There should be a steady increase in pH and serum bicarbonate as therapy progresses. Kussmaul respirations should abate and abdominal pain resolve. Persistent acidosis may indicate inadequate insulin or fluid therapy, infection, or, rarely, lactic acidosis. Urine ketones may be positive long after ketoacidosis has resolved because the nitroprusside reaction routinely used to measure urine ketones by dipstick only measures acetoacetate. During DKA, most excess ketones are ß-hydroxybutyrate, which increases the normal ratio to acetoacetate from 3:1 to as high as 8:1. With resolution of the acidosis, ß-hydroxybutyrate converts to acetoacetate, which is excreted into the urine and detected by the dipstick test. Therefore, persistent ketonuria may not accurately reflect the degree of clinical improvement and should not be relied upon as an indicator of therapeutic failure.

All patients with DKA should be checked for initiating events that triggered the metabolic decompensation, for example, an infection.

DKA PROTOCOL. (See Table 583–6 .)

Even though DKA can be of variable severity, a common approach to all cases simplifies the therapeutic regimen and can be safely used for most children. Fluids are best calculated based on weight, not body surface area (M^2), because heights are rarely available for the calculation. The Milwaukee protocol has been used for more than 20 yr in a large clinic setting with no deaths and no neurologic sequelae in any child treated with this protocol. It can be used for children of all ages and with all degrees of DKA. It is designed to restore most electrolyte deficits, to reverse the acidosis, and to rehydrate the moderately ill child in about 24?hr. A standard water deficit (85?mL/kg) is assumed. This amount, when added to maintenance, yields about 4?L/M^2 for children of all sizes. Children with milder DKA recover in 10 to 20?hr (and need less total IV fluid before switching to oral intake), whereas those with more severe DKA require 30 to 36?hr with this protocol. Any child can be easily transitioned to oral intake and subcutaneous insulin when DKA has essentially resolved (total CO_2 > 15?mEq/L; pH > 7.30; sodium stable between 135–145?mEq/L; no emesis). The IV is capped, and the first dose of subcutaneous insulin is given with a meal. Children with mild DKA can often be discharged after a few hours of therapy in the emergency department if adequate follow-up is provided.

A flow sheet is mandatory for accurate monitoring of changes in acidosis, electrolytes, fluid balance, and clinical status, especially if the patient is transferred from the emergency department to an inpatient setting with new caretakers. This flow sheet is best implemented by a central computer system, which allows for rapid update and wide availability of results, as well as rule-driven highlighting of critical values. A paper flow sheet suffices if it stays with the patient, is kept current, and is reviewed frequently by the physician. Any flow sheet should include columns for serial electrolytes, pH, glucose, and fluid balance. Blood testing should occur hourly for children with severe DKA and every 3–4?hr for those with mild to moderate DKA.

Even though this protocol has a long safety record, one must continue to *closely monitor each patient*. For all but the mildest cases, this should include frequent neurologic checks for any signs of increasing intracranial pressure, such as a change of consciousness, depressed respiration, worsening headache, bradycardia, apnea,

pupillary changes, papilledema, posturing, or seizures. Mannitol must be readily available for use at the earliest sign of cerebral edema. One must also keep informed of the laboratory changes; hypokalemia or hypoglycemia can occur rapidly. Children with moderate to severe DKA have a higher overall risk and should be treated in an intensive care environment. Finally, this protocol may not be appropriate for some patients such as the severely hypernatremic child (corrected sodium greater than 150?mEq/L) who may need slower rehydration with a longer duration of isotonic fluids.

Some residual ß-cell function is seen even in children presenting with DKA. This function may improve as the child recovers from the effects of hyperglycemia and elevated counter-regulatory hormones. This residual secretion may necessitate a reduction in the initial total subcutaneous insulin dose used in the first few days of therapy.

NONKETOTIC HYPEROSMOLAR COMA.

This syndrome is characterized by severe hyperglycemia (blood glucose greater than 800?mg/dL), absence of or only slight ketosis, nonketotic acidosis, severe dehydration, depressed sensorium or frank coma, and various neurologic signs that may include grand mal seizures, hyperthermia, hemiparesis, and positive Babinski signs. Respirations are usually shallow, but coexistent metabolic (lactic) acidosis may be manifested by Kussmaul breathing. Serum osmolarity is commonly 350?mOsm/kg or greater. This condition is uncommon in children; among adults, mortality rates have been as high as 40–70%, possibly in part because of delays in recognition and institution of appropriate therapy. In children, there has been a high incidence of pre-existing neurologic damage. Profound hyperglycemia may develop over a period of days and, initially, the obligatory osmotic polyuria and dehydration may be partially compensated for by increasing fluid intake. With progression of disease, thirst becomes impaired, possibly because of alteration of the hypothalamic thirst center by hyperosmolarity and, in some instances, because of a pre-existing defect in the hypothalamic osmoregulating mechanism.

The low production of ketones is attributed mainly to the hyperosmolarity, which in vitro blunts the lipolytic effect of epinephrine and the antilipolytic effect of residual insulin; blunting of lipolysis by the therapeutic use of ß-adrenergic blockers may contribute to the syndrome. Depression of consciousness is

closely correlated with the degree of hyperosmolarity in this condition as well as in DKA; hemoconcentration may also predispose to cerebral arterial and venous thromboses.

Treatment of nonketotic hyperosmolar coma is directed at rapid repletion of the vascular volume deficit and very slow correction of the hyperosmolar state. One-half isotonic saline (0.45% NaCl; some use normal saline) is administered at a rate estimated to replace 50% of the volume deficit in the first 12?hr, and the remainder is administered during the ensuing 24?hr. The rate of infusion and the saline concentration are titrated to result in a slow decline of serum osmolality. When the blood glucose concentration approaches 300?mg/dL, the hydrating fluid should be changed to 5% dextrose in 0.2 normal (N) saline. Approximately 20?mEq/L of potassium chloride should be added to each of these fluids to prevent hypokalemia. Serum potassium and plasma glucose concentrations should be monitored at 2-hr intervals for the first 12?hr and at 4-hr intervals for the next 24?hr to permit appropriate adjustments of administered potassium and insulin.

Insulin can be given by continuous IV infusion beginning with the 2nd?hr of fluid therapy. Blood glucose may decrease dramatically with fluid therapy alone. IV insulin dose should be 0.05?U/kg/h of regular (fast-acting) rather than 0.l U/kg/h as advocated for patients with DKA.

NUTRITIONAL MANAGEMENT.

Nutrition plays an essential role in the management of patients with type 1 DM. This is of critical importance during childhood and adolescence, when appropriate energy intake is required to meet the needs for energy expenditure, growth, and pubertal development. Nutritional treatment alone or in combination with appropriate insulin therapy averts or relieves symptoms of hyperglycemia in diabetic patients. Moreover, nutritional practices may influence the development of long-term complications of diabetes (i.e., diabetic nephropathy). There are no special nutritional requirements for the diabetic child other than those for optimal growth and development. In outlining nutritional requirements for the child on the basis of age, sex, weight, and activity, food preferences, including any based on cultural and ethnic backgrounds, must be considered.

Total recommended *caloric intake* is based on size or surface area and can be obtained from standard tables (Tables 583–7 and 583–8). The caloric mixture should comprise approximately 55% carbohydrate, 30% fat, and 15% protein. Approximately 70% of the carbohydrate content should be derived from complex carbohydrates such as starch; intake of sucrose and highly refined sugars should be limited. Complex carbohydrates require prolonged digestion and absorption so that plasma glucose levels increase slowly, whereas glucose from refined sugars,

TABLE 583.2-8 -- Summary of Nutrition Guidelines for Children and/or Adolescents with Type 1 Diabetes Mellitus

Nutrition Care Plan

Promotes optimal compliance.

Incorporates goals of management: normal growth and development, control of blood glucose, maintenance of optimal nutritional status, and prevention of complications. Uses staged approach.

Nutrient Recommendations and Distribution

Nutrient	(%) of Calories	Recommended Daily Intake
Carbohydrate	Will vary	High fiber, especially soluble fiber; optimal amount unknown
Fiber	>20?g per day	
Protein	12–20	
Fat	<30	
Saturated	<10	
Polyunsaturated	6–8	
Monounsaturated	Remainder of fat allowance	
Cholesterol		300?mg
Sodium		Avoid excessive; limit to 3,000–4,000?mg if hypertensive

Additional Recommendations

Energy: If using measured diet, re-evaluate prescribed energy level at least every 3 mo.

Protein: High-protein intakes may contribute to diabetic nephropathy. Low intakes may reverse preclinical nephropathy. Therefore, 12–20% of energy is recommended; lower end of range is preferred. In guiding toward the end of the range, a staged approach is useful.

Alcohol: Safe use of moderate alcohol consumption should be taught as routine anticipatory guidance as early as junior high.

Snacks: Snacks vary according to individual needs (generally three snacks per day for children; midafternoon and bedtime snacks for junior high children or teens).

Alternative sweeteners: Use of a variety of sweeteners is suggested.

Educational techniques: No single technique is superior. Choice of educational method used should be based on patient needs. Knowledge of variety of techniques is important. Follow-up education and support are required.

Eating disorders: Best treatment is prevention. Unexplained poor control or severe hypoglycemia may indicate a potential eating disorder.

Exercise: Education is vital to prevent delayed or immediate hypoglycemia and to prevent worsened hyperglycemia and ketosis.

From Connell JE, Thomas-Doberson D: Nutritional management of children and adolescents with insulin-dependent diabetes mellitus: A review by the Diabetes Care and Education Dietetic Practice Group. J Am Diet Assoc 1991;91:1556.

including carbonated beverages, is rapidly absorbed and may cause wide swings in

the metabolic pattern; carbonated beverages should be sugar-free. Priority should be given to total calories and total carbohydrate consumed rather than its source. *Carbohydrate counting* has become a mainstay in the nutrition education and management of patients with DM. Each carbohydrate exchange unit is 15?g. Patients and their families are provided with information regarding the carbohydrate contents of different foods and food label reading. This allows patients to adjust their insulin dosage to their mealtime carbohydrate intake. The use of carbohydrate counting and insulin to carbohydrate ratios and the use of fast-acting insulin analogs and long-acting basal insulins (ultralente and glargine) provide many children with less rigid meal planning. Flexibility in the use of insulin in relation to carbohydrate content of food improves the quality of life.

Although in children there is concern about the potential cumulative effect of saccharin, available data do not support an association of moderate amounts with bladder cancer. Other non-nutritive sweeteners such as aspartame are used in a variety of products. Sorbitol and xylitol should not be used as artificial sweeteners; they are products of the polyol pathway and are implicated in some of the complications of diabetes.

Diets with *high fiber content* are useful in improving control of blood glucose. Moderate amounts of sucrose consumed with fiber-rich foods such as whole meal bread may have no more glycemic effect than their low-fiber, sugar-free equivalents. The

concept of biologic equivalence or of a “glycemic index” of foods is under investigation.

The *intake of fat* is adjusted so that the polyunsaturated:saturated ratio is increased to about 1.2:1.0, in contrast to the estimated American average of 0.3:1.0. Dietary fats derived from animal sources are, therefore, reduced and replaced by polyunsaturated fats from vegetable sources. Substituting margarine for butter, vegetable oil for animal oils in cooking, and lean cuts of meat, poultry, and fish for fatty meats, such as bacon, is advisable. The intake of cholesterol is also reduced by these measures and by limiting the number of egg yolks consumed. These simple measures reduce serum low-density lipoprotein cholesterol, a predisposing factor to atherosclerotic disease. Less than 10% of calories should be derived from saturated fats, up to 10% from polyunsaturated fats, and the remaining fat-derived calories from monounsaturated fats. Table 583–8 summarizes current nutritional guidelines.

The total daily caloric intake is divided to provide 20% at breakfast, 20% at lunch, and 30% at dinner, leaving 10% for each of the midmorning, midafternoon, and evening snacks, if they are desired. In older children, the midmorning snack may be omitted and its caloric equivalent added to lunch. Special brochures and pamphlets describing sample meal plans for children are usually available from regional diabetes associations; their use should be encouraged as part of the educational process. Meal plans are often based on groups of food exchanges; within each of the exchange lists of the foods that are principal sources of carbohydrates, proteins, and fats, there is a wide variety of foods that can be substituted or exchanged. There are few restrictions so that each child can select a diet based on personal taste or preferences with the help of the physician or dietitian, or both. Emphasis should be placed on regularity of food intake and on constancy of carbohydrate intake. Occasional excesses for birthdays and other parties are permissible and tolerated to not foster rebellion and stealth in obtaining desired food. Cakes and even candies are permissible on special occasions as long as the food exchange value and carbohydrate content are adjusted in the meal plan. Adjustments in meal planning must constantly be made to meet the needs as well as the desires of each child, although a consistent eating pattern with appropriate supplements for exercise, the pubertal growth spurt, and pregnancy in a diabetic adolescent are important for metabolic control. There is also an increased frequency of eating disorders among young women with diabetes. Thus, expectations and educational advice regarding nutrition must be dealt with in a sensitive careful manner, especially in adolescents.

MONITORING.

Success in the daily management of the diabetic child can be measured by the competence acquired by the family, and subsequently by the child, in assuming responsibility for daily “diabetic care.” Their initial and ongoing instruction in conjunction with their supervised experience can lead to a sense of confidence in making intermittent adjustments in insulin dosage for dietary deviations, unusual physical activity, and even for some minor intercurrent illnesses, as well as for otherwise unexplained repeated hypoglycemic reactions and excessive glucosuria. Such acceptance of responsibility should make them relatively independent of the physician for their ordinary care. The physician must maintain ongoing interested supervision and shared responsibility with the family and the child.

Self-monitoring of blood glucose (SMBG) is an essential component of managing diabetes and necessitates a regimen that includes measurements of blood glucose and, at times, urinary ketones, as well as the keeping of a standardized record of these results and the corresponding data of dietary deviations, unusual physical activity, hypoglycemic reactions, intercurrent illness, the daily dose of insulin, and other items of possible relevance. When the physician mistrusts the patient's record, physicians may make their own evaluations. If these data are counter to those in the parent or child's report, the physician can then attempt to clarify the situation in a manner that does not undermine their mutual confidence.

Daily blood glucose monitoring has been markedly enhanced by the availability of strips impregnated with glucose oxidase that permit blood glucose measurement from a drop of blood. A portable calibrated reflectance meter can approximate the blood glucose concentration accurately. Many meters contain a memory “chip” enabling recall of each measurement, its average over a given interval, and the ability to display the pattern on a computer screen. Such information is a useful educational tool for verifying degree of control and modifying recommended regimens. A small spring-loaded device that automates capillary blood letting (lancing device) in a relatively painless fashion is commercially available. Parents and patients should be taught to use these devices and measure blood glucose three to four times daily—before breakfast, lunch, and supper, and at bedtime. Initially, at diagnosis, the blood glucose measurement should also be performed at 12 am and 3 am to exclude inappropriate nocturnal hypoglycemia and avoid the Somogyi phenomenon. Ideally, the blood glucose concentration should range from approximately 80?mg/dL in the fasting state to 140?mg/dL after meals. In practice,

however, a range of 60–220?mg/dL is acceptable, based on age of the patient. Blood glucose measurements that are consistently at or outside these limits, in the absence of an identifiable cause such as exercise or dietary indiscretion, are an indication for a change in the insulin dose. If the fasting blood glucose is high, the evening dose of long-acting insulin is increased by 10–15% and/or the insulin (lispro or aspart) coverage for bedtime snack may be considered; if the noon glucose level exceeds set limits, the morning fast-acting insulin (lispro or aspart) is increased by 10–15%; if the presupper glucose is high, the noon dose fast-acting insulin is increased by 10–15%; and if the prebedtime glucose measurement is high, the presupper dose of fast-acting insulin is increased by 10–15%. Similarly, reductions in the insulin type and dose should be made if the corresponding blood glucose measurements are consistently below desirable limits.

A minimum of four daily blood glucose measurements should be performed. However, some children and adolescents may need to have more frequent blood glucose monitoring based on their level of physical activity and history of frequent hypoglycemic reactions. Families should be encouraged to become sufficiently knowledgeable about managing their diabetes. They can maintain near-normal glycemia for prolonged periods of time by self-monitoring of blood glucose levels before and 2?hr after meals, and in conjunction with multiple daily injections of insulin, adjusted as necessary, can maintain near-normal glycemia for prolonged periods.

The *continuous glucose monitoring system (CGMS)* records data obtained from a subcutaneous sensor every 5?min for up to 72?hr and provides the clinician with a continuous profile of tissue glucose levels. The interstitial glucose levels lag 13?min behind the blood glucose values independent of level in ambient blood glucose. The CGMS values tend to have high correlation coefficient for blood glucose values ranging between 40 and 400?mg/dL. CGMS is minimally invasive and entails the placement of a small, subcutaneous catheter that can be easily worn by adults and children. The system provides information that allows the patient and healthcare team to adjust the insulin regimen and the nutrition plan to improve glycemic control. CGMS can be helpful in detecting asymptomatic nocturnal hypoglycemia as well as in lowering HbA_{1c} values without increasing the risk for severe hypoglycemia. While there are potential pitfalls in CGMS use including suboptimal compliance, human error, incorrect technique and sensor failure, the implementation of CGMS in ambulatory diabetes practice allows the clinician to diagnose abnormal glycemic patterns in a more precise manner.

Glucowatch Biographer uses reverse iontophoresis to analyze the glucose content of interstitial fluid, which is extracted through a membrane patch on the patient's wrist beneath the Glucowatch device. Glucowatch provides realtime interstitial fluid glucose values, in the range of 40–400?mg/dL, that are the average of blood glucose values for the preceding 20?min. Glucose values in the range of 70–280?mg/dL have the highest correlation coefficient with blood glucose values. Additionally, Glucowatch alarm can be set for monitoring nocturnal hypoglycemia as needed.

A reliable index of long-term glycemic control is provided by measurement of *glycosylated hemoglobin*. HbA_{1c} represents the fraction of hemoglobin to which glucose has been nonenzymatically attached in the bloodstream. The formation of HbA_{1c} is a slow reaction that is dependent on the prevailing concentration of blood glucose; it continues irreversibly throughout the red blood cell's life span of approximately 120 days. The higher the blood glucose concentration and the longer the red blood cell's exposure to it, the higher is the fraction of HbA_{1c} , which is expressed as a percentage of total hemoglobin. Because a blood sample at any given time contains a mixture of red blood cells of varying ages, exposed for varying times to varying blood glucose concentrations, an HbA_{1c} measurement reflects the average blood glucose concentration of the preceding 2–3 mo. When measured by standardized methods to remove labile forms, the fraction of HbA_{1c} is not influenced by an isolated episode of hyperglycemia. Consequently, as an index of long-term glycemic control, a measurement of HbA_{1c} is superior to measurements of glycosuria or a single blood glucose determination. It is recommended that HbA_{1c} measurements be obtained three to four times per year to obtain a profile of long-term glycemic control. The more consistently lower the HbA_{1c} level, and hence the better the metabolic control, the more likely it is that microvascular complications such as retinopathy and nephropathy will be less severe, delayed in appearance, or avoided. Depending on the method used for determination, HbA_{1c} values may be spuriously elevated in thalassemia (or other conditions with elevated hemoglobin F) and spuriously lower in sickle cell disease. Although values of HbA_{1c} may vary according to the method used for measurement, in nondiabetic individuals, the HbA_{1c} fraction is usually less than 6%; in diabetics, values of 6–8.5% represent good metabolic control, values of 9–10%, fair control, and values of 11% or higher, poor control (Table 583–9).

EXERCISE.

No form of exercise, including competitive sports, should be forbidden to the diabetic child. A major complication of exercise in diabetic patients is the presence of a hypoglycemic reaction during or within hours after exercise. If hypoglycemia does not occur with exercise, adjustments in diet or insulin are not necessary, and glucoregulation is likely to be improved through the increased utilization of glucose by muscles. The major contributing factor to hypoglycemia with exercise is an increased rate of absorption of insulin from its injection site.

TABLE 583.2-9 -- Target Premeal and 30-Day Average Blood Glucose Ranges and the Corresponding Hemoglobin A_{1c} for each Age Group

Age Group (yr)	Target Premeal BG Range (mg/dL)	30-Day Average BG Range (mg/dL)	Target HbA_{1c} (%)
<5	100–200	180–250	7.5–9.0
5 to 11	80–150	150–200	6.5–8.0

12 to 15	80–130	120–180	6.0–7.5
16 to 18	70–120	100–150	5.5–7.0

In our laboratory the nondiabetic reference range for HbA_{1c} is 4.5–5.7% (95% confidence interval).

BG, blood glucose; HBA_{1c} , hemoglobin A_{1c} .

Higher insulin levels dampen hepatic glucose production so that it is inadequate to meet the increased glucose utilization of exercising muscle. Regular exercise also improves glucoregulation by increasing insulin receptors. In patients who are in poor metabolic control, vigorous exercise may precipitate ketoacidosis because of the exercise-induced increase in the counter-regulatory hormones.

In anticipation of vigorous exercise, one additional carbohydrate exchange may be taken before exercise, and glucose from orange juice, carbonated nondietetic beverage, or candy should be available during and after exercise. With experience and trial and error, each patient, guided by the physician, should develop an appropriate regimen for regularly planned exercise that is frequently associated with hypoglycemia; in such instances, the total dose of insulin may be reduced by about 10–15% on the day of the scheduled exercise. Prolonged exercise, such as long-distance running may require reduction of as much as 50% or more of the usual insulin dose.

BENEFITS OF IMPROVED GLYCEMIC CONTROL.

The DCCT established conclusively the association between higher glucose levels and long-term microvascular complications. Intensive management produced dramatic reductions of retinopathy, nephropathy, and neuropathy by 47–76%. The data from the adolescent cohort demonstrated the same degree of improvement and the same relationship between the outcome measures of microvascular complications. Adolescents gained more weight and experienced significantly more frequent episodes of severe hypoglycemia and ketoacidosis than did adults. Other studies of children and adolescents have not documented increased frequency or severity of hypoglycemia.

The beneficial effect of intensified treatment was determined by the degree of blood glucose normalization, independent of the type of intensified treatment used. Frequent blood glucose monitoring was considered an important factor in achieving better glycemic control for the intensively treated adolescents and adults. Patients who were intensively treated had individualized glucose targets, frequent adjustments based on ongoing capillary blood glucose monitoring, and a team approach that focused on the person with diabetes as the prime initiator of ambulatory care. Care was constantly adjusted toward reaching normal or near normal glycemic goals, while avoiding or minimizing severe episodes of hypoglycemia. Teaching emphasized a proactive (preventive) approach to blood glucose fluctuations with constant readjustment (reactive approach) to counterbalance any high or low blood glucose readings. Target blood glucose goals were adjusted upward if hypoglycemia could not be prevented.

Total duration of diabetes contributes to development and severity of complications. Nonetheless, many professionals have concerns about applying the results of the DCCT to preschool-aged children, who often have hypoglycemia unawareness with unique safety issues and to prepubertal school-aged children, who were not included in the DCCT.

CURRENT INTENSIVE INSULIN REPLACEMENT REGIMENS.

The goal of physiologic insulin replacement for type 1 DM is accomplished with short-acting insulins that more closely mimic the sharp increase and short duration of pancreatic insulin secreted with nutrient intake. The rapid-acting insulin analog lispro has superior pharmacokinetic properties for the control of postprandial glucose. Improved postprandial glucose responses occur when treated with twice-daily injections (conventional insulin, CI), multiple daily injections (MDI), or CSII. The use of lispro or aspart insulin reduces the frequency of between-meal hypoglycemic events, especially when it is carefully balanced with the carbohydrate content of meal. This has improved how insulin is given to toddlers as well as when a flexible meal plan is desired.

The carbohydrate content of food does not influence glycemic control if premeal rapid-acting insulin (bolus) is adjusted to the

carbohydrate content of meal. Wide variations in carbohydrate intake do not modify long-acting (ultralente/glargine) or basal insulin requirement. Insulin replacement strategies stress the importance of administering smaller doses of insulin throughout the day. This approach allows insulin doses to be changed as needed to correct hyperglycemia, supplement for additional anticipated carbohydrate intake, or subtract for exercise. Indeed, bolus-basal treatment with multiple injections is better adapted to the physiologic profiles of insulin and glucose and can therefore provide better glycemic control than the conventional two- to three-dose regimen. Age-adjusted and individualized insulin to carbohydrate ratios and insulin dosage adjustment algorithms have been developed to normalize elevated blood glucose levels and to compensate for alterations in carbohydrate intake. The use of flexible multiple daily injections (FMDIs) and CSII in children with type 1 DM improves glycemic control without an increase in the incidence of severe hypoglycemia.

HYPOGLYCEMIC REACTIONS.

Hypoglycemia is the major limitation to tight control of glucose levels. Once injected, insulin absorption and action are independent of the glucose level, thus creating a unique risk of hypoglycemia from an unbalanced insulin effect. Insulin analogs may help reduce but cannot eliminate this risk. Most children with type 1 diabetes can expect mild hypoglycemia each week, moderate hypoglycemia a few times each year, and severe hypoglycemia every few years. These episodes are usually not

predictable, although exercise, delayed meals or snacks, and wide swings in glucose levels increase the risk. Infants and toddlers are at higher risk because they have more variable meals and activity levels, are unable to recognize early signs of hypoglycemia, and are limited in their ability to seek a source of oral glucose to reverse the hypoglycemia. The very young have an increased risk of permanently reduced cognitive function as a long-term sequela of severe hypoglycemia. For this reason, a more relaxed degree of glucose control is necessary until the child matures (see Table 583–9).

Hypoglycemia can occur at any time of day or night. Early symptoms and signs (mild hypoglycemia) may occur with a sudden decrease in blood glucose to levels that do not meet standard criteria for hypoglycemia in nondiabetic children (see Chapter 81). The child may show pallor, sweating, apprehension or fussiness, hunger, tremor, and tachycardia, all due to the surge in catecholamines as the body attempts to counter the excessive insulin effect. Behavioral changes such as tearfulness, irritability, aggression, and naughtiness are more prevalent in children. As glucose levels decline further, cerebral glucopenia occurs with drowsiness, personality changes, mental confusion, impaired judgment (moderate hypoglycemia), progressing to an inability to seek help, and seizures or coma (severe hypoglycemia). Prolonged severe hypoglycemia can result in a depressed sensorium or strokelike focal motor deficits that persist after the hypoglycemia has resolved. Although permanent sequelae are rare, severe hypoglycemia is frightening for the child and family, and can result in a significant reluctance to attempt even moderate glycemic control afterward.

Important counter-regulatory hormones in children include growth hormone, cortisol, epinephrine, and glucagon. The latter two seem more critical in the older child. Many older patients with long-standing type 1 diabetes lose their ability to secrete glucagon in response to hypoglycemia. In the young adult, epinephrine deficiency may also develop as part of a general autonomic neuropathy. This substantially increases the risk of hypoglycemia because the early warning signals of a declining glucose level are due to catecholamine release. Recurrent hypoglycemic episodes associated with tight metabolic control may aggravate partial counter-regulatory deficiencies, producing a syndrome of *hypoglycemia unawareness* and reduced ability to restore euglycemia (hypoglycemia-associated autonomic failure). Avoidance of hypoglycemia allows some recovery from this unawareness syndrome.

The most important factors in the management of hypoglycemia are an understanding by the patient and family of the symptoms and signs of the reaction and an anticipation of known precipitating factors such as gym or sports activities. Tighter glucose control increases the risk. Families should be taught to look for typical hypoglycemic scenarios or patterns in the home blood glucose log, so that they may adjust the insulin dose and avert predictable episodes. A source of emergency glucose should be available at all times and places, including at school and during visits to friends. If possible, it is initially important to document the hypoglycemia before treating, because some symptoms may not always be due to hypoglycemia. Most families and children develop a good sense for true hypoglycemic episodes and can institute treatment before testing. Any child suspected of having a moderate to severe hypoglycemic episode should also be treated before testing. It is important not to give too much glucose; 5–10?g should be given as juice or a sugar-containing carbonated beverage or candy and the blood glucose checked 15–20 minutes later. Patients, parents, and teachers should also be instructed in the administration of *glucagon* when the child cannot take glucose orally. An injection kit should be kept at home and school. The intramuscular dose is 0.5?mg if the child weighs less than 20?kg and 1.0?mg if more than 20?kg. This produces a brief release of glucose from the liver. Glucagon often causes emesis, which precludes giving oral supplementation if the blood glucose declines after the glucagon effect has waned. Caretakers must then be prepared to take the child to the hospital for IV glucose administration, if necessary.

THE SOMOGYI PHENOMENON, THE DAWN PHENOMENON, AND BRITTLE DIABETES.

There are several reasons that blood glucose levels increase in the early morning hours before breakfast. The most common is a simple decline in insulin levels and is seen in many children using NPH or lente as the basal insulin at supper or bedtime. This usually results in routinely elevated morning glucose. The ***dawn phenomenon*** is thought to be due mainly to overnight growth hormone secretion and increased insulin clearance. It is a normal physiologic process seen in most nondiabetic adolescents, who compensate with more insulin output. A child with type 1 diabetes cannot compensate and may actually have declining insulin levels if using evening NPH or lente. The dawn phenomenon is usually recurrent and modestly elevates most morning glucose levels.

Rarely, high morning glucose is due to the Somogyi phenomenon, a theoretical rebound from late night or early morning hypoglycemia, thought to be due to an exaggerated counter-regulatory response. It is unlikely to be a common cause, in that most children remain hypoglycemic once nighttime glucose levels decline. Continuous glucose monitoring systems should allow clarification of ambiguously elevated morning glucose levels.

The term *brittle diabetes* has been used to describe the child, usually an adolescent female, with unexplained wide fluctuations in blood glucose, often with recurrent DKA, who is on large doses of insulin. An inherent physiologic abnormality is rarely present because these children usually show normal insulin responsiveness when in the hospital environment. Psychosocial or psychiatric problems, including eating disorders, and dysfunctional family dynamics are usually present, which preclude effective diabetes therapy. Hospitalization is usually needed to confirm the environmental effect, and aggressive psychosocial or psychiatric evaluation is essential.

BEHAVIORAL/PSYCHOLOGICAL ASPECTS AND EATING DISORDERS.

Diabetes in a child affects the lifestyle and interpersonal relationships of the entire family. Feelings of anxiety and guilt are common in parents. Similar feelings, coupled with denial and rejection, are equally common in children,

---

particularly during the rebellious teenage years. Family conflict has been associated with poor treatment adherence and poor metabolic control among youths with type 1 DM. No specific personality disorder or psychopathology is characteristic of diabetes;

similar feelings are observed in families with other chronic disorders.

Nonadherence. Family conflict, denial, and feelings of anxiety find expression in nonadherence to instructions regarding nutritional and insulin therapy and in noncompliance with self-monitoring. Deliberate overdosage with insulin, resulting in hypoglycemia, or omission of insulin, often in association with excesses in nutritional intake and resulting in ketoacidosis, may be pleas for psychological help or manipulative attempts to escape an environment perceived as undesirable or intolerable; occasionally, they may be manifestations of suicidal intent. Frequent admissions to the hospital for ketoacidosis or hypoglycemia should arouse suspicion of an underlying emotional conflict. Overprotection on the part of parents is common and often is not in the best interest of the patient. Feelings of being different or of being alone, or both, are common and may be justified in view of the restrictive schedules imposed by testing of urine and blood, administration of insulin, and nutritional limitations. Furthermore, concern about the likelihood of complications developing and the decreased life span of patients with diabetes fosters anxiety. Unfortunately, misinformation abounds about the risks of the development of diabetes in siblings or offspring and of pregnancy in young diabetic women. Even appropriate information often causes further anxiety.

Many of these problems can be averted through continued empathic counseling based on correct information and attempts to build attitudes of normality in the patient and a feeling of being a productive member of society. Recognizing the potential impact of these problems, peer discussion groups have been organized in many locales; feelings of isolation and frustration tend to be lessened by the sharing of common problems. Summer camps for diabetic children afford an excellent opportunity for learning and sharing under expert supervision. Education about the pathophysiology of diabetes, insulin dose, technique of administration, nutrition, exercise, and hypoglycemic reactions can be reinforced by medical and paramedical personnel. The presence of numerous peers with similar problems offers new insights to the diabetic child. Residential treatment for children and adolescents with difficult to manage type 1 DM is an option available only in some centers.

Anxiety and Depression. It has been shown that there are significant correlations between a poor metabolic control and depressive symptoms, a high level of anxiety, or a previous psychiatric diagnosis. In a similar way, poor metabolic control is related to higher levels of personal, social, school maladjustment, or family environment dissatisfaction. It is estimated that between 20–26% of adolescent patients may develop major depressive disorder (MDD), which is similar to the occurrence rate of MDD in nondiabetic adolescents. The course characteristics of MDD in young diabetic subjects and psychiatric control subjects appear to be similar; however, eventual propensity of diabetic youths for more protracted depressions is greater and there is higher risk of recurrence among young diabetic females. Therefore, the health care providers managing a child or adolescent with diabetes should be aware of their pivotal role as counselor and advisor and should closely monitor the mental health of patients with diabetes.

Fear of Self-injecting and Self-testing. Extreme fear of self-injecting (FSI) insulin (injection phobia) is likely to compromise glycemic control as well as emotional well-being. Likewise, fear of finger pricks can be a source of distress and may seriously hamper self-management. Children and adolescents with FSI either omit insulin dosing and/or refuse to rotate their injection sites because repeated injections in the same site is associated with less pain sensation. Failure to rotate injection sites results in subcutaneous scar formation (lipohypertrophy). Insulin injection into the lipohypertrophic skin is usually associated with poor insulin absorption and/or insulin leakage with resultant suboptimal glycemic control.

Eating Disorders. Treatment of type 1 DM involves constant monitoring of food intake. In addition, improved glycemic control is commonly associated with increased weight gain. In adolescent females, these two factors, along with individual, familial, and socioeconomic factors, can lead to an increased incidence of both nonspecific and specific eating disorders, which can disrupt glycemic control and increase the risk of long-term complications. Eating disorders and subthreshold eating disorders are almost twice as common in adolescent females with type 1 DM as in their nondiabetic peers. The reports of the frequencies of specific (anorexia or bulimia nervosa) eating disorders vary between 1–6.9% among female patients with type 1 DM. The prevalence of nonspecific and subthreshold eating disorders is 9% and 14%, respectively. About 11% of type 1 DM adolescent females take less insulin than prescribed to lose weight. Among adolescent females with an eating disorder, about 42% of patients misuse insulin, whereas the estimates of insulin misuse prevalence in subthreshold and nondisordered eating groups are 18% and 6%, respectively. While there is little information regarding the prevalence of eating disorders among male adolescents with type 1 DM, available data suggest normal eating attitudes in this group of patients. Among healthy adolescent males who participate in wrestling, however, the drive to lose weight has led to the seasonal, transient development of abnormal eating attitudes and behaviors, which may lead to insulin dose omission in order to lose weight.

When behavioral/psychological problems and/or eating disorders are assumed to be responsible for poor compliance with the medical regimen, referral for psychological evaluation and management is indicated. Children and adolescents with injection phobia and fear of self-testing can be counseled by a trained behavioral therapist and benefit from such techniques as desensitization and biofeedback to attenuate pain sensation and psychological distress associated these procedures. Behavioral therapists and psychologists usually form part of the pediatric diabetes team in most centers, and can help assess and manage emotional and behavioral disorders in diabetic children.

MANAGEMENT DURING INFECTIONS.

While infections are no more common in diabetic children than in nondiabetic ones, they can often disrupt glucose control and may precipitate DKA. In addition, the diabetic child is at increased risk of dehydration if hyperglycemia causes an osmotic diuresis or if ketosis causes emesis. Counter-regulatory hormones associated with stress blunt insulin action and elevate glucose levels. If anorexia occurs, however, lack of caloric intake increases the risk of hypoglycemia. Although children younger than 3 yr tend to become hypoglycemic and older children tend toward hyperglycemia, the overall effect is unpredictable. Therefore, frequent blood glucose monitoring and adjustment of insulin doses are essential elements of sick day guidelines (Table 583–10).

The overall goals are to maintain hydration, control glucose levels, and avoid ketoacidosis. This can usually be done at home if proper sick day guidelines are followed and with telephone contact with health care providers. The family should

seek advice if home treatment does not control ketonuria, hyperglycemia, or hypoglycemia, or if the child shows signs of dehydration. A child with large ketonuria and emesis should be seen in the emergency department for a general examination, to evaluate hydration, and to determine whether ketoacidosis is present by checking serum electrolytes, glucose, pH, and total CO_2 . A child whose blood glucose declines to less than 50–60?mg/dL (2.8–3.3?mmol/L) and who cannot maintain oral intake may need IV glucose, especially if further insulin is needed to control ketonemia.

TABLE 583.2-10 -- **Guidelines for Sick Day Management**

Urine Ketone Status	Glucose Testing and Extra Insulin	Rapid-Acting Insulin Correction Doses[*]	Comments
Neg or small[†]	q2?hr	q2?hr for glucose > 250?mg/dL	Check ketones every other void.
Moderate to large[‡]	q1?hr	q1?hr for glucose > 250?mg/dL	Check ketones each void. Go to hospital if emesis occurs.
Basal insulin: glargine or ultralente basal insulin should be given at the usual dose and time. NPH and lente should be reduced by one half if blood glucose <150?mg/dL and the oral intake is limited.			
Oral fluids: sugar free if blood glucose > 250?mg/dL (14?mmol/L); sugar-containing if blood glucose <250?mg/dL.			
Call physician or nurse if blood glucose remains elevated after three extra doses; if blood glucose remains less than 70?mg/dL and child cannot take oral supplement; if dehydration occurs.			

**Give insulin based on individualized dosing schedule. Also give usual dose for carbohydrate intake if glucose > 150?mg/dL.*
† For home serum ketones <1.5?mmol/L per commercial kit.
‡ For home serum ketones > 1.5?mmol/L.

MANAGEMENT DURING SURGERY.

Surgery can disrupt glucose control in the same way as can intercurrent infections. Stress hormones associated with the underlying condition as well as with surgery itself decrease insulin sensitivity. This increases glucose levels, exacerbates fluid losses, and may initiate DKA. On the other hand, caloric intake is usually restricted, which decreases glucose levels. The net effect is as difficult to predict as during an infection. Vigilant monitoring and frequent insulin adjustments are required to maintain euglycemia and avoid ketosis.

Maintaining glucose control and avoiding DKA are best accomplished with IV insulin and fluids. A simple insulin adjustment scale based on the patient's weight and blood glucose level can be used in most situations (Table 583–11). The IV insulin is continued after surgery as the child begins to take oral fluids; the IV fluids can be steadily decreased as oral intake increases. When full oral intake is achieved, the IV may be capped and subcutaneous insulin begun. When surgery is elective, it is best performed early in the day, allowing the patient maximal recovery time to restart oral intake and subcutaneous insulin therapy. When elective surgery is brief (less than 1?hr) and full oral intake is expected shortly afterward, one may simply monitor the blood glucose hourly and give a rapid analog according to the child's home glucose correction scale. If glargine is used as the basal insulin, a full dose is given the evening before planned surgery. If NPH, lente, or ultralente are used, one half of the morning dose is given before surgery. The child should not be discharged until blood glucose levels are stable and oral intake is tolerated.

Long-Term Complications: Relation to Glycemic Control.

The increasingly prolonged survival of the diabetic child is associated with an increasing prevalence of complications. Complications of DM can be divided into three major categories—(1) microvascular complications, specifically retinopathy and nephropathy; (2) macrovascular complications, particularly accelerated coronary artery disease, cerebrovascular disease, and peripheral vascular disease; and (3) neuropathies, both peripheral and autonomic, affecting a variety of organs and systems. Cataracts affect the lens.

Diabetic retinopathy is the leading cause of blindness in the United States in adults aged 20–65 yr. The risk of diabetic retinopathy after 15 yr duration of diabetes is 98% for individuals with type 1 DM and 78% for those with type 2 DM. Lens opacities (due to glycation of tissue proteins and activation of polyol pathway) are present in at least 5% of those younger

TABLE 583.2-11 -- **Guidelines for Intravenous Insulin Coverage During Surgery**

Blood Glucose Level (mg/dL)	Insulin Infusion (units/kg/hr)	Blood Glucose Monitoring
<120	0.00	1?hr
121–200	0.03	2?hr
200–300	0.06	2?hr
300–400	0.08	1?hr*
400	0.10	1?hr*

An infusion of 5% glucose and 0.45% saline solution with 20?mEq/L of potassium acetate is given at 1.5 times maintenance rate.

Check urine ketones.

than 19 yr of age. Although the metabolic control has an impact on the development of this complication, genetic factors also have a role, because only 50% of patients develop proliferative retinopathy. The earliest clinically apparent manifestations of diabetic retinopathy are classified as nonproliferative or background diabetic retinopathy—microaneurysms, dot and blot hemorrhages, hard and soft exudates, venous dilation and beading, and intraretinal microvascular abnormalities. These changes do not impair vision. The more severe form is proliferative diabetic retinopathy—manifested by neovascularization, fibrous proliferation, and preretinal and vitreous hemorrhages. Proliferative retinopathy, if not treated, is relentlessly progressive and impairs vision, leading to blindness. The mainstay of treatment is panretinal laser photocoagulation. In advanced diabetic eye disease—manifested by severe vitreous hemorrhage or fibrosis, often with retinal detachment—vitrectomy is an important therapeutic modality. Eventually, the eye disease becomes quiescent, a stage termed *involutional retinopathy*. A separate subtype of retinopathy is diabetic maculopathy, which is manifested by severe macular edema impairing central vision, for which focal laser photocoagulation may be effective.

Guidelines suggest that diabetic patients have an initial dilated and comprehensive examination by an ophthalmologist shortly after the diagnosis of diabetes is made in patients with type 2 DM, and within 3–5 yr after the onset of type 1 DM (but not before age 10 yr). Any patients with visual symptoms or abnormalities should be referred for ophthalmologic evaluation. Subsequent evaluations for both type 1 and type 2 DM patients should be repeated annually by an ophthalmologist who is experienced in diagnosing the presence of diabetic retinopathy and is knowledgeable about its management.

Diabetic nephropathy is the leading known cause of end-stage renal disease (ESRD) in the United States. Most ESRD from diabetic nephropathy is preventable. Diabetic nephropathy affects 20–30% of patients with type 1 DM and 15–20% of type 2 DM patients 20 yr after onset. The mean 5-yr life expectancy for patients with diabetes-related ESRD is less than 20%. The increased mortality risk in long-term type 1 DM may be due to nephropathy, which may account for about 50% of deaths. The risk of nephropathy increases with duration of diabetes, up until 25–30 yr duration (after which this complication rarely begins), degree of metabolic control, and genetic predisposition to essential hypertension. Only 30–40% of patients affected by type 1 DM eventually experience ESRD. The glycation of tissue proteins results in glomerular basement membrane thickening. The course of diabetic nephropathy is slow. An increased urinary albumin excretion rate (AER) of 30–300?mg/24?hr (20–200?µg/min)—so-called microalbuminuria—can be detected and constitutes an early stage of nephropathy from intermittent to persistent (incipient), which is commonly associated with glomerular hyperfiltration and blood pressure elevation. As nephropathy evolves to early overt stage with proteinuria (AER > 300?mg/24?hr or > 200?µg/min), it is

accompanied by hypertension. Advanced stage nephropathy is defined by a progressive decline in renal function (declining glomerular filtration rate and elevation of serum blood urea and creatinine), progressive proteinuria, and hypertension. Progression to ESRD is recognized by the appearance of uremia, the nephritic syndrome, and the need for renal replacement (transplantation or dialysis).

Screening for diabetic nephropathy is a routine aspect of diabetes care. The American Diabetes Association (ADA) recommends yearly screening for individuals with type 2 DM and yearly screening for those with type 1 DM after 5 yr duration of disease (but not before puberty). Twenty-four hour AER (urinary albumin and creatinine) or timed (overnight) urinary AER are acceptable techniques. Positive results should be confirmed by a second measurement of AER because of the high variability of albumin excretion in patients with diabetes. Short-term hyperglycemia, exercise, urinary tract infections, marked hypertension, heart failure, and acute febrile illness can cause transient elevation urinary albumin excretion. There is marked day-to-day variability in albumin excretion, so at least two of three collections done in a 3–6 mo period should show elevated levels before a patient is diagnosed with microalbuminuria and treatment is started. Once albuminuria is diagnosed, a number of factors attenuate the effect of hyperfiltration on kidneys: (1) meticulous control of hyperglycemia, (2) aggressive control of systemic blood pressure, (3) selective control of arteriolar dilation by use of angiotensin-converting enzyme (ACE) inhibitors (thus decreasing transglomerular capillary pressure), and (4) dietary protein restriction (because high protein intake increases renal perfusion rate).

Diabetic Neuropathy. Both the peripheral and autonomic nervous systems can be involved, and adolescents with diabetes can show early evidence of neuropathy. This complication can be traced to the metabolic effects of hyperglycemia and/or other effects of insulin deficiency on the various constituents of the peripheral nerve. The polyol pathway, nonenzymatic glycation, and/or disturbances of myoinositol metabolism affecting one or more cell types in the multicellular constituents of the peripheral nerve appear likely to have an inciting role. The role of other factors, such as possible direct neurotrophic effects of insulin, insulin-related growth factors, nitric oxide, and stress proteins, seems to be relevant. Peripheral neuropathy may first present in some adolescents with long-standing history of diabetes. Using quantitative sensory testing (QST), abnormal cutaneous thermal perception is a common finding in both upper and lower limbs in neurologically asymptomatic young

diabetic patients. Heat-induced pain threshold in the hand is correlated with the duration of the diabetes. There is no correlation between QST scores and metabolic control. Subclinical motor nerve impairment as manifested by reduced sensory nerve conduction velocity and sensory nerve action potential amplitude can be detected during late puberty and after puberty in about 10% of adolescents. Poor metabolic control during puberty appears to induce deteriorating peripheral neural function in young patients. An early sign of autonomic neuropathy such as decreased heart rate variability may present in adolescents with a history of long-standing disease and poor metabolic control. A number of therapeutic strategies have been attempted with variable results. These treatment modalities include (1) improvement in metabolic control, (2) use of aldose reductase inhibitors to reduce by-products of polyol pathway, (3) use of a-lipoic acid (an antioxidant) that enhances tissue nitric oxide and its metabolites, and use of anticonvulsants (e.g., lorazepam, valproate, carbamazepine, tiagabine, and topiramate) for treatment of neuropathic pain.

Other complications in diabetic children include dwarfism associated with a glycogen-laden enlarged liver (Mauriac syndrome), osteopenia, and a *syndrome of limited joint mobility* associated with tight, waxy skin, growth impairment, and maturational delay. The Mauriac syndrome is related to under-insulinization; it is rare because of the availability of the longer-acting insulins. Clinical features of Mauriac syndrome include moon face, protuberant abdomen, proximal muscle wasting, and enlarged liver due to fat and glycogen infiltration. The syndrome of limited joint mobility is frequently associated with the early development of diabetic microvascular complications, such as retinopathy and nephropathy, which may appear before 18 yr of age.

Prognosis.

Type 1 DM is not a benign disease. It has been estimated that average life span of individuals with diabetes is about 10 yr shorter than nondiabetic population. Visual, renal, neuropathic, and other complications were relatively frequent. Furthermore, although diabetic children eventually attain a height within the normal adult range, puberty may be delayed, and the final height may be less than the genetic potential. From studies in identical twins, it is apparent that despite seemingly satisfactory control, the diabetic twin manifests delayed puberty and a substantial reduction in height when onset of disease occurs before puberty. These observations indicate that, in the past, conventional criteria for judging control were inadequate and that adequate control of type 1 DM was almost never achieved by routine means.

The introduction of portable devices (insulin pumps) that can be programmed to provide CSII with meal-related pulses is one approach to the resolution of these long-term problems. In selected individuals, nearly normal patterns of blood glucose and other indices of metabolic control, including HbA_{1c} , have been maintained for several years. This approach, however, should be reserved for highly motivated persons committed to rigorous self-monitoring of blood glucose, who are alert to the potential complications such as mechanical failure of the infusion device causing hyperglycemia or hypoglycemia and to infections at the site of catheter insertion.

The changing pattern of metabolic control is having a profound influence on reducing the incidence and the severity of certain complications. For example, after 20 yr of diabetes, there is a decline in the incidence of nephropathy in type 1 DM in Sweden among children diagnosed in 1971–1975 compared with those diagnosed in the preceding decade. Also, in most patients with microalbuminuria in whom it was possible to obtain good glycemic control, microalbuminuria disappeared. Thus, prognosis is related to metabolic control.

Pancreas and Islet Transplantation and Regeneration.

In an attempt to cure type 1 DM, transplantation of a segment of the pancreas or of isolated islets has been performed. These procedures are both technically demanding and associated with the risks of disease recurrence and complications of rejection and its treatment by immunosuppression. Hence, segmental pancreas transplantation is generally performed in association with transplantation of a kidney for a patient with ESRD due to diabetic nephropathy in which the immunosuppressive regimen is indicated for the renal transplantation. Several thousand such transplants have been performed in adults. With experience and newer immunosuppressive agents, functional survival of the pancreatic graft may be achieved for up to several years, during which time patients may be in metabolic control with no or minimal exogenous insulin and reversal of some of the microvascular complications. However, because children and adolescents with DM are not likely to have ESRD from their diabetes, pancreas transplantation as a primary treatment in children cannot be recommended or its risk justified. Complications of immunosuppression include the development of malignancy. Some antirejection drugs, notably cyclosporine and tacrolimus, are themselves toxic to the islets of Langerhans, impairing insulin secretion and even causing diabetes. Attempts to transplant isolated islets have been equally challenging because of rejection. Research continues to improve techniques for the yield, viability, and reduction of immunogenicity of the islets of Langerhans for transplantation.

An islet transplantation strategy (Edmonton-protocol) infuses isolated pancreatic islets into the portal vein of a group of adults with type 1 DM. This therapeutic strategy also involved the use of a new generation of immunosuppressive medications that apparently have lower side-effect profiles than other drugs. Out of 15 consecutive patients with at least 1 yr of follow-up after the initial transplant, 12 (80%) were insulin independent at 1 yr. Although patients experienced minimal side effects from immunosuppressive medications, some complications associated with islet transplantation procedures were observed that included portal vein thrombosis, bleeding related to the percutaneous portal vein access, an expanding intrahepatic and subscapular hemorrhage on anticoagulation (requiring transfusion and surgery). Elevated liver function test results were found in 46% of subjects but resolved in all.

Regeneration of islets is an approach that could potentially cure type 1 DM. It is classified into three categories:

1. In vitro therapy using transplanted cultured cells, including embryonic stem cells, pancreatic stem cells, and ß cell lines, in conjunction with immunosuppressive therapy or immunoisolation.
2. Ex vivo regeneration therapy, patients' own cells, such as bone marrow stem cells, which are transiently removed and induced to differentiate into ß cells in vitro. At present, however, insulin-producing cells cannot be generated from

bone marrow stem cells.
3. In vivo regeneration therapy, in which impaired tissues regenerate from patients' own cells in vivo. ß-cell neogenesis from non–ß cells and ß-cell proliferation in vivo has been considered, particularly as regeneration therapies for type 2 DM.

Regeneration therapy of pancreatic ß cells can be combined with various other therapeutic strategies, including islet transplantation, cell-based therapy, gene therapy, and drug therapy to promote ß-cell proliferation and neogenesis, and it is hoped that these strategies will, in the future, provide a cure for diabetes.

583.3 Type 2 Diabetes Mellitus

Type 2 DM is considered a polygenic disease aggravated by environmental factors, such as low physical activity or hypercaloric lipid-rich diet. Obese type 2 diabetic patients show insulin resistance of skeletal muscle, enhanced hepatic glucose production, and decreased glucose-induced insulin secretion. Over time, hyperglycemia worsens, a phenomenon that has been attributed to deleterious effect of chronic hyperglycemia (glucotoxicity) or chronic hyperlipidemia (lipotoxicity) on ß-cell function and is often accompanied by increased triglyceride content and decreased insulin gene expression. This category of diabetes has been considered a disease of obese and sedentary adults after age 40 yr. Numerous studies describe type 2 DM in Native American youth, as well as their African American, Hispanic, and white peers. Pediatric type 2 DM in adolescents represents one of the most rapidly growing forms of diabetes. The incidence of type 2 DM among children diagnosed with diabetes at one medical center increased from 4% before 1992 to 16% in 1994. In that report, among those aged 10–19 yr, type 2 DM accounted for one third of all newly diagnosed children with diabetes in 1994. Overall, the incidence of adolescent type 2 DM increased 10-fold from 0.7 to 7.2/100,000 per year in the reported Midwest metropolitan area. The mean age of presentation was 13.8 yr; most children were markedly obese. We have observed a more than 10-fold increase in incidence of type 2 DM (from less than 2% to about 22% of new cases of DM) in children aged 10–18 yr in the past decade. African American, Hispanic, and white adolescents are usually affected. African Americans constitute almost 70% of the type 2 DM cases.

The epidemic of type 2 DM in children and adolescents parallels the emergence of the obesity epidemic. Although obesity itself is associated with insulin resistance, diabetes does not develop until there is some degree of failure of insulin secretion. Thus, when measured, insulin secretion in response to glucose or other stimuli is always lower in persons with type 2 DM than in control subjects matched for age, sex, weight, and equivalent glucose concentration. Although it is generally believed that autoimmune destruction of pancreatic ß cells does not occur in type 2 DM diabetes, autoimmune markers of type 1 DM, namely GAD65, ICA512, and IAA may be positive in up to one third of the cases of adolescent type 2 DM. These findings reflect a broad spectrum of pancreatic and peripheral abnormalities that could lead to type 2 DM and the presence of these autoimmune markers does not rule out type 2 DM in children and adolescents.

In type 2 DM, insulin deficiency is rarely absolute, so patients usually do not need insulin to survive, although glycemic control may be improved by exogenous insulin. DKA, when it occurs, is associated with the stress of another illness such as severe infection and may resolve when the stressful illness resolves. DKA tends to be more common in African American patients than in other ethnic groups. Most patients with type 2 DM remain asymptomatic for months to years because hyperglycemia is so moderate that symptoms are not as dramatic as the polyuria and weight loss accompanying type 1 DM; weight gain may continue. The prolonged hyperglycemia may be accompanied, in time, by the development of microvascular and macrovascular complications. Type 2 DM occurs more frequently in certain ethnic or racial groups, such as Pacific Islanders, Pima Indians, and African Americans. It also occurs in individuals with hypertension and dyslipidemia. Type 2 DM has a stronger genetic component than in type 1 DM. Concordance rates among identical twins are virtually 100% for type 2 and only 30–50% for type 1 DM. The genetic basis for type 2 DM is complex and incompletely defined; no single identified defect predominates as does the HLA association with type 1 DM. *Acanthosis nigricans* may be a marker for insulin resistance, hyperinsulinemia, and eventually type 2 DM. Hirsutism, associated with the *polycystic ovary syndrome,* premature adrenarche, or mild mutations in steroidogenic enzymes, is frequently associated with insulin resistance in children and adolescents and may be a forerunner of the future development of type 2 DM (see Chapter 580).

Type A insulin resistance with acanthosis nigricans is characterized by severe insulin resistance and acanthosis nigricans in the absence of obesity or lipoatrophy; affected females also have hyperandrogenism, possibly as a secondary manifestation of the hyperinsulinemia with stimulation of androgen synthesis by ovarian theca cells (see Chapter 580). Glucose intolerance is variable and includes symptomatic diabetes. The hyperandrogenism presents with clinical and biochemical findings suggestive of polycystic ovary syndrome. Some patients, predominantly African American females with obesity, acanthosis nigricans, and accelerated growth suggestive of gigantism, may represent insulin resistance due to obesity with downregulation of the insulin receptor. The gigantism may represent a “spillover” effect of insulin acting via the insulin growth factor 1 receptor rather than as the insulin receptor.

Treatment.

Nutritional education is a cornerstone of therapy for children and adolescents with type 2 DM. These children often come from a household environment with a poor understanding of healthy eating habits. Commonly observed behaviors include skipping meals, heavy snacking, and excessive daily television viewing, video game playing, and computer use. Adolescents engage in non-appetite–based eating (i.e., emotional eating, television-cued eating, boredom) and cyclic dieting (“yo-yo”). Treatment for type 2 DM should target weight

---

loss and increasing physical activity as an initial approach. These approaches, however, are frequently unsuccessful.

The only universally accepted pharmacologic agent available for type 2 DM in children is insulin. Although optimal glycemic control can be obtained with insulin therapy, it often results in significant weight gain. At the time of diagnosis and depending on presentation, insulin therapy may be necessary, but with close medical follow-up, it can often be reduced, substituted, or even discontinued within a few

weeks after glucose control is achieved. Once a patient is nonacidotic and well hydrated, an effective therapy is to initiate insulin management in combination with metformin (a biguanide), which decreases hepatic glucose production. The starting dose of metformin is usually 500?mg, twice daily with meals. Metformin is contraindicated if there is significant renal or liver impairment. Therefore, proper assessment of liver and renal function is essential before initiating therapy. A class of pharmaceutical agents, the thiozolidinediones, enhances insulin action by decreasing hepatic glucose production and facilitating glucose disposal in muscle and fat. Because they act as insulin enhancers, they are used in conjunction with exogenous insulin and metformin. These agents, the “glitazones,” are not approved for use in children in the United States; undue liver toxicity has been reported.

Prevention.

The difficulties in achieving good glucose control and preventing diabetes complications make prevention a compelling strategy. This is particularly true for type 2 DM, which is clearly linked to modifiable risk factors, i.e., obesity, and a sedentary lifestyle. The Diabetes Prevention Program (DPP) was designed to prevent or delay the development of type 2 DM in adult individuals at high risk for its development by virtue of their having impaired glucose tolerance (IGT). The DPP results demonstrated that intensified lifestyle or drug intervention in individuals with IGT prevented or delayed the onset of type 2 DM. The results were striking. Lifestyle intervention reduced diabetes incidence by 58%; metformin reduced the incidence by 31% compared with placebo. The effects were similar for men and women and for all racial and ethnic groups. Lifestyle interventions are believed to have similar beneficial effects in obese adolescents with IGT.

Impaired Glucose Tolerance.

The term *impaired glucose tolerance* (IGT) is suggested as a replacement for terms such as asymptomatic diabetes, chemical diabetes, subclinical diabetes, borderline diabetes, or latent diabetes in order to avoid the stigma associated with the term *diabetes mellitus,* which may influence the choice of vocation, eligibility for health or life insurance, and self-image. Although IGT represents a biochemical intermediate between normal glucose metabolism and that of diabetes, experience has shown that few children with IGT go on to acquire diabetes; estimates range from 0–10%. There is disagreement about whether the degree of glucose intolerance is useful as a prognostic index of the likelihood of progression, but there is evidence that among the few instances of progression, the insulin response during glucose tolerance testing is severely impaired. Islet cell or insulin autoantibodies as well as the HLA-DR3 or -DR4 haplotype are commonly found in those who go on to develop clinical diabetes. In most obese children with IGT, insulin responses during oral glucose tolerance tests are higher than the mean for age-adjusted but not weight-adjusted control subjects; these individuals have some resistance to the effects of insulin rather than a total inability to secrete it.

In healthy nondiabetic children, the glucose response during an oral glucose tolerance test is similar at all ages. In contrast, plasma insulin responses during the test increase progressively within the age span of about 3–15 yr and are significantly higher during puberty so that interpretation of these responses requires comparison with age- and puberty-adjusted responses.

The performance of the glucose tolerance test should be standardized according to currently accepted criteria. These include at least 3 days of a well-balanced diet containing approximately 50% of calories from carbohydrates, fasting from midnight until the time of the test in the morning, and a dose of glucose for the test of 1.75?g/kg but not more than 75?g. Plasma samples are obtained before ingestion of the glucose and at 1, 2, and 3?hr thereafter. The arbitrarily designated response to the test that identifies IGT is a fasting plasma glucose value of less than 126?mg/dL and a value at 2?hr of more than 140?mg/dL but less than 200?mg/dL (see Table 583–2). Determination of serum insulin responses during the glucose tolerance test is not a prerequisite for reaching a diagnosis; the magnitude of the response, however, may have prognostic value.

In children with IGT but without fasting hyperglycemia, repeated oral glucose tolerance tests are not recommended. Investigations in such children indicate that the degree of impaired glucose tolerance tends to remain stable or may actually improve over a period of years, except in patients with markedly subnormal insulin responses. Consequently, apart from reduction in weight for the obese child, no therapy is indicated. In particular, the use of oral hypoglycemic agents should be restricted to investigational studies. If fasting hyperglycemia or characteristic symptoms of diabetes develop, the affected children have the characteristics of type 2 DM, previously known as NIDDM (see Table 583–1).

583.4 Other Specific Types of Diabetes

Genetic Defects of ß-Cell Function

MATURITY-ONSET DIABETES OF YOUTH.

This subtype of DM contains a group of heterogeneous genetic and clinical entities, which are characterized by early onset between the ages of 9 and 25 yr of age, autosomal dominant inheritance (AD), and a primary defect in insulin secretion. Three types of maturity-onset diabetes of youth (MODY) genes have been identified. MODY 1 results from a mutation in the hepatocyte nuclear factor (HNF)-4a gene located on the long arm of chromosome 20. MODY 2 is caused by a mutation in the gene for glucokinase located on the short arm of chromosome 7. MODY 3 is due to a gene mutation for HNF-1a located on the long arm of chromosome 12. Strict criteria for the diagnosis of MODY include diabetes in at least three generations with AD transmission and diagnosis before age 25 yr in at least one affected subject.

Mutations in the glucokinase gene responsible for MODY 2 result in mild, chronic hyperglycemia due to mild reductions in pancreatic ß-cell response to glucose. As a result, this is usually a relatively mild form of diabetes with mild fasting hyperglycemia and IGT in the majority of patients, which can be treated with small doses of exogenously administered insulin. Patients affected with mutations in HNF-4a or -1a show more severe abnormalities of carbohydrate metabolism, varying from impaired glucose tolerance to severe diabetes and often progressing from a mild to a severe form over time. About one third of these patients will require insulin and are prone to the development of vascular complications. Patients with MODY 2 and defects in the glucokinase gene may demonstrate normal insulin responses to

intravenous glucose when blood glucose concentrations are maintained at greater than 7?mM. Defective glucokinase activity has been likened to a defective glucose sensor in the pancreatic ß cell. By contrast, patients with MODY 1 and MODY 3 have more severe impairment of insulin secretion, and this defect cannot be overcome by priming with glucose infusion.

By definition, the absence of a family history suggestive of AD inheritance makes a diagnosis of MODY virtually untenable. In such circumstances, the appearance of diabetes in a relatively young person would most likely represent evolving type 1 DM,

and therefore evaluation for markers of autoimmunity are warranted. Milder, slowly evolving type 1 DM could be confused with type 2 DM.

Distinction among the present forms of MODY has clinical relevance in counseling because of the lesser likelihood of vascular complications in MODY 2 and, therefore, the need to treat appropriately with insulin, if necessary, in patients with MODY 1 and MODY 3. Molecular analysis for the currently known gene mutations on chromosomes 20, 7, and 12 are likely to become available for routine clinical use in the future to facilitate diagnosis and management. An additional form of MODY due to heterozygous mutation in a homeodomain transcription factor called insulin promoter factor-1 has also been described.

Primary or secondary defects in *GLUT-2 type of glucose transporter,* an insulin-independent form, may also be associated with diabetes. GLUT-2 rapidly transports glucose into ß cells for subsequent phosphorylation by glucokinase, which eventually leads to insulin secretion. The phenomenon of glucose toxicity, in which there is a loss or reduction in the first-phase insulin response to a pulse of glucose, may be the result of secondary downregulation of GLUT-2 transporters.

MODY also may be a manifestation of a *polymorphism in the glycogen synthase gene.* This enzyme is crucially important for storage of glucose as glycogen in muscle. Patients with this defect are notable for marked resistance to insulin and hypertension as well as a strong family history of diabetes.

MITOCHONDRIAL GENE DEFECTS.

Point mutations in mitochondrial DNA are sometimes associated with DM and deafness. One mutation is identical to the mutation in MELAS (myopathy, encephalopathy, lactic acidosis, and stroke–like syndrome), but this syndrome is not associated with diabetes so that the phenotypic expression of the same defect varies. Another form of IDDM, sometimes associated with mitochondrial mutations, is the Wolfram syndrome.

Wolfram syndrome is characterized by diabetes insipidus, DM, optic atrophy, and deafness—thus the acronym DIDMOAD. Wolfram syndrome is caused by mitochondrial dysfunction, possibly by a nuclear gene mapped to the short arm of chromosome 4. Some patients with diabetes appear to have severe insulinopenia, whereas others have significant insulin secretion as judged by C-peptide. In two patients who were tested, islet cell antibodies were not detected, whereas HLA typing revealed DR2, which is generally considered “protective” for diabetes. In some patients with diabetes and deafness, a mutation in mitochondrial tRNA has been detected; in others, this mutation is absent. The overall prevalence is 1/770,000. The sequence of appearance of the stigmata was as follows: nonautoimmune IDDM in the 1st decade; central diabetes insipidus and sensorineural deafness in two thirds to three fourths of the patients in the 2nd decade; renal tract anomalies in about one half of the patients in the 3rd decade; and neurologic complications such as cerebellar ataxia and myoclonus in one half to two thirds of the patients in the 4th decade. Other features included primary gonadal atrophy in the majority of males and a progressive neurodegenerative course with neurorespiratory death at a median age of 30 yr. Absence of maternal diabetes or deafness and absence of the previously reported mitochondrial gene defect suggests autosomal recessive inheritance.

DIABETES MELLITUS OF THE NEWBORN

Transient. Onset of persistent type 1 DM before the age of 6 mo is most unusual. The syndrome of transient DM in the newborn infant has its onset in the 1st wk of life and persists only several weeks to months before spontaneous resolution. It occurs most often in infants who are small for gestational age and is characterized by hyperglycemia and pronounced glycosuria, resulting in severe dehydration and, at times, metabolic acidosis but with only minimal or no ketonemia or ketonuria. Insulin responses to glucose or tolbutamide are low to absent; basal plasma insulin concentrations are normal. After spontaneous recovery, the insulin responses to these same stimuli are brisk and normal, implying a functional delay in ß-cell maturation with spontaneous resolution. Occurrence of the syndrome in consecutive siblings has been reported. Abnormalities of chromosome 6 are common in transient neonatal DM. There are also reports of patients with classic type 1 DM who formerly had transient diabetes of the newborn. It remains to be determined whether this association of transient diabetes in the newborn followed much later in life by classic type 1 DM is a chance occurrence or causally related. This syndrome should be distinguished from severe hyperglycemia that may occur in hypertonic dehydration; this condition usually occurs in infants beyond the newborn period who respond promptly to rehydration with a minimal requirement for insulin.

Administration of insulin is mandatory during the active phase of DM in the newborn. One to 2?U/kg/24?hr of an intermediate-acting insulin in two divided doses usually results in dramatic improvement and accelerated growth and gain in weight. Attempts at gradually reducing the dose of insulin may be made as soon as recurrent hypoglycemia becomes manifested or after 2 mo of age.

Permanent. DM in the newborn period may be permanent if associated with the rare syndrome of pancreatic agenesis. Long-term follow-up of a cohort of patients with neonatal diabetes revealed that almost one half had permanent diabetes, one third had transient diabetes, and about one fourth had transient diabetes that recurred when they were 7–20 yr old. The majority of all these infants were small at birth. Instances of affected twins and families with more than one affected infant have been reported. Some cases of permanent neonatal DM are initially euglycemic and present within the first month of life.

ABNORMALITIES OF THE INSULIN GENE.

Diabetes of variable degrees may also result from *defects in the insulin gene* from faulty processing of proinsulin to insulin, an autosomal dominant defect, to various amino acid substitutions that impair the effectiveness of insulin at the receptor level. However, these defects are notable for the high concentration of insulin as measured by radioimmunoassay, whereas defects in glucokinase, MODY-1, MODY-3, and GLUT-2 are characterized by relative or absolute deficiency of insulin secretion for the prevailing glucose concentrations.

Genetic Defects of Insulin Action.

Two mutations in the insulin receptor gene with relevance for children are leprechaunism and Rabson-Mendenhall syndrome.

LEPRECHAUNISM.

This is a syndrome characterized by intrauterine growth retardation, fasting hypoglycemia, and postprandial hyperglycemia in association with profound resistance to insulin, whose serum concentrations may be 100-fold that of comparable age-matched infants during an oral glucose tolerance test. Various defects of the insulin receptor have been described, thereby attesting to the important role of insulin and its receptor in fetal growth and possibly in morphogenesis. However, even probable complete absence of functional insulin receptors due to homozygous inheritance of a missense mutation in the insulin-receptor gene resulted in normal organogenesis and a liveborn infant who had a severe form of leprechaunism. Most of these patients die in the 1st yr of life.

RABSON-MENDENHALL SYNDROME.

This entity is defined by clinical manifestations that appear to be intermediate between those of acanthosis nigricans with insulin resistance type A and leprechaunism. The features include extreme insulin resistance, acanthosis nigricans, abnormalities of the teeth and nails, and pineal hyperplasia. It is not clear whether this syndrome is entirely distinct from leprechaunism; however, patients with Rabson-Mendenhall tend to live beyond the 1st yr of life. Defects in the insulin-receptor gene have been described in this syndrome.

Cystic Fibrosis-Related Diabetes.

Because of improvements in the medical care of children with cystic fibrosis (CF), many survive

to the late teenage and early adult years. On the other hand, as the annual screening of patients for diabetes among CF centers has become routine, the number of CF-related diabetes (CFRD) cases has almost more than doubled. It is estimated that up to 25% of adolescents with CF have diabetes. The care of these patients is very different from that of patients with type 1 or type 2 DM, because CFRD patients have distinct pathophysiology and complicated nutritional and medical problems.

Patients with CFRD are slender and have insulin deficiency. The clinical presentation is similar to that of type 2 DM in that the onset of the disease is insidious and the occurrence of ketoacidosis is rare. Islet antibody titers are negative. The prevalence of microvascular complications in CFRD in relationship to duration of diabetes, glycemic control, and pulmonary diseases are not well characterized. Macrovascular complications do not appear to be of concern in CFRD. Several factors unique to CF influence both the onset and the course of diabetes: (1) frequent acute or chronic infections are associated with waxing and waning of insulin resistance; (2) energy needs are increased because of infection and pulmonary disease; (3) malnutrition is associated with poor survival; (4) malabsorption is caused by pancreatic exocrine insufficiency, despite enzyme supplementation; (5) altered nutrient absorption is caused by abnormal intestinal transit time; (6) liver disease is present; (7) anorexia and nausea are common as a result of illness, gastroesophageal reflux, delayed gastric emptying, intestinal obstruction, increased work of breathing, and psychosocial factors; (8) there is a wide variation in daily food intake based on the patient's acute health status; and (9) insulin and glucagon secretion are impaired.

In the pancreas, exocrine tissue is replaced by fibrosis and fat; many of the pancreatic islets are destroyed. The remaining islets demonstrate diminished numbers of ß-, a-, and pancreatic polypeptide-secreting cells. Secretion of the islet hormones insulin, glucagon, and pancreatic polypeptide is impaired in patients with CF in response to a variety of secretagogues. It has been suggested that insulin resistance may also play a role in the development of CFRD, especially in the setting of acute infection.

In Denmark, oral glucose tolerance screening of the entire CF population demonstrated no diabetes in patients younger than 10 yr, 12% diabetes in patients aged 10–19 yr, and 48% diabetes in adults aged 20 yr and older. At a Midwestern center where routine annual oral glucose tolerance screening is performed, only about one half of children and one fourth of adults have normal glucose tolerance. Diabetes is seen in 9% of CF children, 26% of adolescents, and 35% of adults aged 20–29 yr. About one third of patients with CFRD have fasting hyperglycemia and two thirds have CFRD without fasting hyperglycemia. The fasting hyperglycemia is exacerbated chronically, or intermittently with infection or glucocorticoid therapy in 3% of children, 11% of adolescents, and 15% of adults.

When hyperglycemia develops, the accompanying metabolic derangements are usually mild and, if insulin therapy becomes necessary, relatively low doses usually suffice for adequate management. Ketoacidosis is uncommon but may occur with progressive deterioration of islet cell function. Treatment with insulin is as outlined for type 1 DM, but dietary management may be limited by the constraints of the primary disturbance.

Autoimmune Diseases.

Chronic lymphocytic thyroiditis (Hashimoto thyroiditis) is frequently associated with

type 1 DM in children (Chapter 559). As many as one in five insulin-dependent diabetic patients may have thyroid antibodies in their serum; the prevalence is 2–20 times greater than that observed in control populations. Only a small proportion of these patients, however, acquire clinical hypothyroidism; the interval between diagnosis of diabetes and thyroid disease averages about 5 yr. Periodic palpation of the thyroid gland is indicated in all diabetic children; if the gland feels firm or enlarged, or both, serum measurements of thyroid antibodies and thyroid-stimulating hormone (TSH) should be obtained. A TSH level of greater than 10?µU/mL indicates existing or incipient thyroid dysfunction that warrants replacement with thyroid hormone. Deceleration in the rate of growth may also be due to thyroid failure and is, in itself, a reason for securing serum measurements of thyroxine and TSH concentrations.

When diabetes and thyroid disease coexist, the possibility of *adrenal insufficiency* should also be considered. It may be heralded by decreasing insulin requirements, increasing pigmentation of the skin and buccal mucosa, salt craving, weakness, asthenia and postural hypotension, or even frank addisonian crisis as evidence of primary adrenal failure. This syndrome is most unusual in the 1st decade of life, but it may become apparent in the 2nd decade or later.

Celiac disease, formerly known as nontropical sprue, another autoimmune disorder, is due to hypersensitivity to dietary gluten that occurs with significant frequency in children with type 1 DM (Chapter 320.8). It is estimated that about 7.0% of children with type 1 DM develop celiac disease within the first 6 yr from the diagnosis. Young children with type 1 DM and celiac disease usually present with gastrointestinal symptoms (abdominal cramping, diarrhea, and gastroesophageal reflux), growth failure due to suboptimal weight gain, and unexplained hypoglycemic reactions due to nutrient malabsorption, whereas adolescents may remain asymptomatic for the most part. The diagnosis of celiac disease is considered if serum antiendomysial and/or tissue transglutaminase antibody titers are positive in the presence of normal serum total IgA level. However, the diagnosis is confirmed on endoscopic evaluation and biopsy of small bowel revealing characteristic histopathologic (atrophic) changes of intestinal villi.

Circulating antibodies to gastric parietal cells and to intrinsic factor are two to three times more common in patients with type 1 DM than in control subjects. There are good correlations of antibodies to gastric parietal cells with atrophic gastritis and of antibodies to intrinsic factor with *malabsorption of vitamin* B_{12} . Although the possibility of megaloblastic anemia should be considered in children with type 1 diabetes, its occurrence is rare.

A *variant of the multiple endocrine deficiency syndrome* is characterized by type 1 diabetes-idiopathic intestinal mucosal atrophy with associated inflammation and severe malabsorption, IgA deficiency, and circulating antibodies to multiple endocrine organs including the thyroid, adrenal, pancreas, parathyroid, and gonads. In addition, nondiabetic family members have an increased frequency of vitiligo, Graves disease, and multiple sclerosis as well as low complement levels and antibodies to endocrine tissues.

Endocrinopathies.

The endocrinopathies listed in Table 583–1 are only rarely encountered as a cause of diabetes in childhood. They may accelerate the manifestations of diabetes in those with inherited or acquired defects in insulin secretion or action.

Drugs.

The immunosuppressive agents cyclosporin and tacrolimus are toxic to ß cells, causing IDDM in a significant proportion of patients treated with these agents. Their toxicity to pancreatic ß cells was a contributing factor in limiting their usefulness to arrest ongoing autoimmune destruction of ß cells. Streptozotocin and the rodenticide Vacor also are toxic to ß cells, causing diabetes.

Genetic Syndromes Associated with Diabetes Mellitus.

A number of rare genetic syndromes associated with IDDM or carbohydrate intolerance have been described (see Table 583–1). These syndromes represent a broad spectrum of diseases ranging from premature cellular aging, as in the Werner and Cockayne syndromes (see Chapter 79), to excessive obesity associated with hyperinsulinism, resistance to insulin action, and carbohydrate intolerance as in the Prader-Willi syndrome (see Chapter 69). Some of these syndromes are characterized by primary disturbances

---

in the insulin receptor or in antibodies to the insulin receptor without any impairment in insulin secretion. Although rare, these syndromes provide unique models to understand the multiple causes of disturbed carbohydrate metabolism from defective insulin secretion or from defective insulin action at the cell receptor or postreceptor level. **REFERENCES**

Part 26 - The Nervous System

Chapter 584 - Neurologic Evaluation

Robert H. A. Haslam

The neurologic evaluation seeks to assess the integrity of the central nervous system (CNS) by means of a thorough history and physical examination and thus to determine the location (and causes) of abnormal function.

HISTORY

The history is the most important component of the evaluation of a child with a neurologic problem. The history should carefully document in chronological order the onset of symptoms and a thorough description of their frequency, duration, and associated characteristics. Most children beyond the age of 3–4 yr are capable of contributing to their history, particularly about facts relating to the present illness. It is essential to obtain a comprehensive review of the function and interaction of all organ systems, because abnormalities of the CNS may initially present with clinical manifestations (e.g., vomiting, pain, constipation, or urinary tract disorders) implicating other systems. A detailed history might suggest that the child's vomiting is due to increased intracranial pressure (ICP), that the pain behind the eye may be caused by migraine headaches or multiple sclerosis, and that the constipation and urinary dribbling may be due to a spinal cord tumor.

It is important to start with a concise description of the chief complaint within its developmental context. For example, parents may be concerned that their child cannot talk. The seriousness of this problem depends on many factors, including the age of the patient, the normal range of language development for age, the parent-child interaction, function of the auditory system, and the intellectual level of the child. A comprehensive understanding of developmental milestones is essential in order to ascertain the relative importance of the parents' observations (see Chapter 9 , Chapter 10 , Chapter 11 , Chapter 12 , Chapter 13 , Chapter 14 , Chapter 15 , Chapter 16).

After the chief complaint and history of present illness are elicited, a review of the pregnancy, labor, and delivery is indicated, particularly if a congenital disorder is suspected (see Chapter 82 , Chapter 83 , Chapter 84 , Chapter 85 , Chapter 86 , Chapter 87 , Chapter 88 , Chapter 89 , Chapter 90 , Chapter 91 , Chapter 92 , Chapter 93 , Chapter 94 , Chapter 95 , Chapter 96 , Chapter 97 , Chapter 98). Was the mother exposed to a viral illness during the pregnancy, and what is the mother's rubella, HIV, and syphilis immune status? The history should also include information about the quantity of cigarette and alcohol consumption, toxin exposure, and drug use (legal and illicit) that are known to have adverse effects on fetal development. Decreased or absent fetal activity may be associated with the congenital myopathies and other neuromuscular disorders. Seizures in utero occasionally occur and suggest placental insufficiency or rare inborn errors of metabolism, such as pyridoxine dependence. Seizure activity in utero is difficult to evaluate, particularly in a primigravida. The fact that fetal seizures occurred during pregnancy is often realized retrospectively after the mother has had an opportunity to observe her infant's seizures. The mother's postpartum health may provide a clue to the cause of her infant's neurologic problem, e.g., maternal fever, drug dependence, cervical or vaginal vesicles (e.g., herpes simplex), hemorrhage, petechiae, or the presence of an abnormal placenta.

The history of the birthweight, length, and head circumference is particularly important. It may be necessary to obtain the infant's hospital records to determine the head circumference, particularly if congenital microcephaly is a consideration, and the Apgar score, for suspected asphyxia. Several indicators of neurologic dysfunction during the newborn period can reliably be obtained from the history. The fact that a full-term infant was unable to breathe spontaneously and required ventilatory assistance may suggest a CNS abnormality. Poor, uncoordinated sucking or a full-term infant who requires an inordinate amount of time to feed suggests a neurologic disorder requiring careful evaluation. If such an infant requires gavage feeding, there is almost certainly a significant problem. All of the aforementioned abnormalities may be common to a premature infant, particularly a very low birthweight infant, and do not necessarily signify a poor neurologic outcome. Additional important information in the newborn period includes the presence of jaundice, its degree, and management. The physician should also attempt to assess the activity, sleep patterns, the nature of the cry, and the general well-being of the newborn infant from the history.

The most important component of a neurologic history is a child's developmental assessment (see Chapters 7 and 16). Careful evaluation of a child's developmental milestones usually determines the presence of a global delay in language and gross and fine motor or social skills or a delay in a particular subset of development. An abnormality in development from birth suggests an intrauterine or perinatal cause. Slowing of the rate of acquisition of skills later in infancy or childhood may imply an acquired abnormality of the nervous system. A loss of skills (regression) over time strongly suggests an underlying degenerative disease of the CNS. The ability of parents to precisely recall the timing of their children's developmental milestones is extremely variable. Some are very reliable and others are uncertain, particularly if the patient in question has a significant neurodevelopmental problem. Table 584–1

provides some guidelines with regard to the upper range of normal skills that are usually recalled by the parents and that, if not present, should alert the physician. It is often helpful to request photographs taken at an earlier age or to review the family's baby book, because milestones for a child may have been dutifully recorded. Parents (particularly mothers) are usually aware when their children have a developmental problem, and the physician should show appropriate concern.

Family history is extremely important in the neurologic evaluation of a child. Parents are sometimes unwilling to discuss family members with debilitating neurologic disorders or may be unaware of them, particularly if they are institutionalized. However, most parents are extremely cooperative in securing medical information about family members, particularly if it may have relevance for their child. The history should document the ages and well-being of all close relatives and the presence of neurologic disease, including epilepsy, migraine, cerebrovascular accidents, developmental delay, and heredofamilial disorders. The sex and age at death of miscarriages or live-born siblings, including the results of postmortem examinations, should be obtained because this information may have a direct bearing on the patient's condition. It should also be determined whether the parents are related, because the incidence of metabolic and degenerative disorders affecting the CNS is increased significantly in children of consanguineous marriages.

TABLE 584-1 -- **Screening Scheme for Developmental Delay: Upper Range**

Age (mo)	Gross Motor	Fine Motor	Social Skills	Language
3	Supports weight on forearms	Opens hands spontaneously	Smiles appropriately	Coos, laughs
6	Sits momentarily	Transfers objects	Shows likes and dislikes	Babbles
9	Pulls to stand	Pincer grasp	Plays pat-a-cake, peek-a-boo	Imitates sounds
12	Walks with one hand held	Releases an object on command	Comes when called	1–2 meaningful words
18	Walks upstairs with assistance	Feeds from a spoon	Mimics actions of others	At least 6 words
24	Runs	Builds a tower of six blocks	Plays with others	2–3 word sentences

Finally, an attempt should be made to learn about the patient as a person. The child's performance in school, both academically and socially, may shed light on the diagnosis, particularly if there has been an abrupt change. A description of the child's personality before and after the onset of symptoms may provide a clue to the cause of the disorder. Discussions with the daycare worker or kindergarten or school teacher may provide useful information that is not available from the parent.

NEUROLOGIC EXAMINATION

Neurologic examination of a child begins at the outset of the interview. Observation during interaction with the parents, while playing, or during the time when little attention is directed to the child can provide useful information (see Chapters 6 and 17). It may be obvious that the child has characteristic facies, an unusual posture, or an abnormality of motor function manifested by a gait disturbance or hemiparesis. Furthermore, much can be learned from observing the child's behavior during the interview. A normally inquisitive child or toddler may play independently but soon wishes to become involved with the interview process. A child with an attention disorder may display inappropriate behaviors in the examining room, whereas a neurologically abnormal child may appear lethargic or disinterested or may show complete lack of awareness of the environment. The degree of interaction between the parent and the child should be noted. Because the neurologic examination of a newborn or premature infant requires a somewhat modified approach from that of an older child, the differences in the examination are highlighted for both age groups (see also Chapters 6 and 83).

The examination should be conducted in a setting that is nonthreatening and enjoyable for a child. The more it seems like a game, the greater will be the degree of cooperation. Children may be most comfortable on a parent's lap or interacting on the floor of the examination room. It is unwise to force a child to sit on the examining table or to demand that all clothes be removed at the beginning of the procedure. Cooperation is essential for a comprehensive neurologic examination; as a child's confidence increases, so too does the level of participation. Several methods may be used to assess *mental status, cognitive function*, and the level of *alertness*, depending on the age of the child. Simple puzzles may be useful. A child's ability to tell a story or to draw a picture is often a powerful method for assessing cognitive function or for determining developmental level. The manner in which a child plays with toys or explores the function of a new object or game is an excellent indicator of intellectual curiosity. The level of alertness of a newborn infant depends on many factors, including the time of the last feeding, the room temperature, and the gestational age. Sequential assessment of the infant is valuable in determining changes in neurologic function. Premature infants of less than 28 wk of gestation do not consistently demonstrate periods of alertness, whereas gentle physical stimulation applied to a slightly older infant arouses the child from sleep and results in a brief period of alertness. Sleep and waking patterns are well developed at term.

The examiner must take advantage of the opportunities provided by the patient; if the circumstances permit, evaluation of muscle power and tone or cerebellar function might precede the cranial nerve examination. However, if a hearing assessment is considered to be important from the historical information, attention should be directed initially to that portion of the examination so that full cooperation can be achieved before the interest and curiosity of the child are lost.

The Head.

The *size* and *shape* of the head should be documented carefully. A tower-head, or oxycephalic skull, suggests premature closure of sutures and is associated with various forms of inherited craniosynostosis (see Chapter 585.12). A broad forehead

may indicate hydrocephalus and a small head microcephaly. The observation of a square or a box-shaped skull should suggest chronic subdural hematomas because the long-standing presence of fluid in the subdural space causes enlargement of the middle fossa. Inspection of the scalp should include observation of the venous pattern, because increased ICP and thrombosis of the superior sagittal sinus can produce marked venous distention.

An infant has two *fontanels* at birth: a diamond-shaped open anterior fontanel that is situated in the midline at the junction of the coronal and sagittal sutures and a posterior fontanel between the intersection of the occipital and parietal bones that may be closed at birth or, at the most, admit the tip of a finger. The posterior fontanel is usually closed and nonpalpable after the first 6–8 wk of life; its persistence suggests underlying hydrocephalus or the possibility of congenital hypothyroidism. The anterior fontanel varies greatly in size, but the usual measurement approximates 2 by 2?cm. The average time of closure is 18 mo, but the fontanel may normally close as early as 9 mo. A very small or absent anterior fontanel at birth may indicate premature fusion of the sutures or microcephaly, whereas a very large fontanel could signify a variety of problems. *The fontanel is normally slightly depressed and pulsatile and is best evaluated when an infant is held upright while asleep or feeding.* A bulging fontanel is a reliable indicator of increased ICP, but vigorous crying can cause a protuberant fontanel in a normal infant.

Palpation of a newborn's skull characteristically shows overriding of the cranial sutures for the first several days of life as a result of the pressures exerted on the skull during its descent through the pelvis. Marked overriding of the sutures beyond a few days is cause for alarm and suggests the possibility of an underlying abnormality of the brain. Palpation may uncover cranial defects or *craniotabes*, a peculiar softening of the parietal bone so that gentle pressure produces a sensation similar to indenting a ping-pong ball. Craniotabes is often associated with prematurity.

Auscultation of the skull is an important adjunct to a neurologic examination. *Cranial bruits* are most prominent over the anterior fontanel, temporal region, or the orbits and are best heard through the diaphragm of the stethoscope. Soft symmetric bruits may be discovered in normal children younger than 4 yr or in association with a febrile illness. Arteriovenous malformations of the middle cerebral artery or vein of Galen may produce a loud bruit. Murmurs arising from the heart or great vessels frequently are transmitted to the cranium. A child with severe anemia is often found to have a skull bruit that disappears when the anemia is corrected. Increased ICP resulting

---

from hydrocephalus, tumor, subdural effusions, or purulent meningitis frequently produces significant intracranial bruits. *Demonstration of a loud or localized bruit is usually significant and warrants further investigation.*

Correct *measurement of the head circumference* is important. It should be performed on every patient, at every visit, and should be recorded on a suitable head growth chart. A nondistensible plastic measuring tape should be used. The tape is placed over the midforehead and is extended circumferentially to include the most prominent portion of the occiput so that the greatest volume of the cranium is measured. The head circumferences of the parents and siblings should also be recorded if the patient is found to have an abnormal skull. Errors in the accurate measurement of a newborn skull are frequent and result from scalp edema, overriding of the sutures, intravenous fluid infiltration, and the presence of a cephalohematoma. The average rate of head growth in a healthy premature infant is 0.5?cm in the first 2 wk, 0.75?cm during the 3rd wk, and 1.0?cm in the 4th wk and thereafter until the 40th wk of development. The head circumference of a term infant at birth measures 34–35?cm, 44?cm by 6 mo, and 47?cm by 1 yr of age (see Chapters 9 and 10).

Cranial Nerves

OLFACTORY NERVE (1).

Anosmia, loss of smell, is most commonly found in association with an upper respiratory tract infection in children and therefore is a transient abnormality. A fracture of the base of the skull and cribriform plate as well as a frontal lobe tumor also may produce anosmia. Occasionally, a child who recovers from purulent meningitis or in whom hydrocephalus develops has a diminished sense of smell. Rarely, anosmia is congenital. Although not a routine component of the examination, smell can be tested reliably as early as the 32nd wk of gestation. Care should be taken to use appropriate stimuli, such as coffee, peppermint, and other substances that are familiar to the child; strongly aromatic substances should be avoided.

OPTIC NERVE (2).

Examination of the optic disc and retina is an important component of the neurologic examination. To visualize a good portion of the retina, dilation of the pupil is necessary. One drop of a combination of 1% cyclopentolate hydrochloride, 2.5% phenylephrine hydrochloride, and 1% tropicamide repeated every 15?min three times effectively produces mydriasis. Mydriatics should not be used if a patient's pupil reaction is necessary to follow the level of consciousness or if a cataract is present. Examination of an infant's retina is enhanced by providing a nipple or soother and by placing the head on one side. The physician gently strokes the patient to maintain arousal, while examining the closest eye. An older child should be placed in the parent's lap and should be distracted by bright objects or toys that are presented during the ophthalmologic examination. The optic nerve is salmon-pink in a child but is gray-white in the newborn, particularly in a blond infant. This normal finding may cause confusion and may lead to the improper diagnosis of optic atrophy.

Papilledema rarely occurs in infancy because the skull sutures are capable of separating to accommodate the expanding brain. Papilledema in an older child may be recognized by the following progressive changes in the optic nerve and surrounding retina (Fig. 584–1):

1. The optic nerve becomes hyperemic.
2. The small capillaries that normally cross the optic nerve are no longer visualized as they become constricted.
3. The larger veins become dilated, and the accompanying arterioles become

constricted.

4. The border of the optic nerve becomes indistinct from the surrounding retina, particularly along the temporal edge.
5. Subhyaloid, flame-shaped hemorrhages appear in the retina surrounding the optic nerve.
6. In some cases, a macular star develops owing to retinal edema in the region of the macula. Visual acuity and color vision remain intact in acute papilledema as contrasted with optic neuritis, but the blind spot is increased in both.

Figure 584-1 *A,* Mild papilledema. Blurred disc margins and venous congestion. *B,* Moderate papilledema. Disc edematous and raised. Vessels buried within substance of nerve tissue. *C,* Severe papilledema. Hemorrhages are evident within disc (*arrow*), and there are microinfarcts (soft exudates) in the nerve fiber layer. *D,* Macular star (*arrow*) with edema residues distributed within the Henle layer of the macula.

Retinal hemorrhages occur in 30–40% of all full-term newborn infants. The hemorrhages are more common after vaginal delivery than after cesarean section and are not associated with birth injury or with neurologic complications. They disappear spontaneously by 1–2 wk of age.

Vision (see also Part XXVIII). Normal 28-wk-old premature infants blink when a bright light is directed to the eyes, and by 32 wk, infants maintain eye closure until the light source is removed. At 37 wk, normal premature infants turn the head and the eyes to a soft light, and by term, visual fixation and the ability to follow a brilliant target are present. During a period of alertness, optokinetic nystagmus can be demonstrated in a newborn. Visual acuity in term infants approximates 20/150 and reaches the adult level of 20/20 by about 6 mo of age. Children who are too young to read the standard letters on the Snellen Eye Chart may learn the “E game” by pointing a finger in the direction that the “E” is oriented. Children as young as 21/2 or 3 yr of age with normal vision identify the objects on the Allen Chart at a distance of 15–20?ft. Peripheral vision may be tested in an infant by bringing an object from behind the patient into the peripheral field of vision that normally produces a visual recognition response. The examiner should be sure that the object rather than a sound produces the visual response.

The *pupil* is difficult to examine in premature infants owing to the poorly pigmented iris and the resistance to lid opening. The pupil reacts to light by the 29th–32nd wk of gestation. The equality of the pupils, their size, and their reaction to light may be affected by drugs, a space-occupying brain lesion, metabolic disorders, and abnormalities of the midbrain and optic nerves.

Horner syndrome is characterized by miosis, ptosis, enophthalmos, and ipsilateral anhidrosis of the face. It may be congenital or may result from a lesion involving the sympathetic nervous system in the brainstem, cervical spinal cord, or the sympathetic plexus in juxtaposition to the carotid artery. Localization of the lesion within the sympathetic nervous system is aided by the pupillary response to a series of topical drugs, including cocaine, epinephrine, hydroxyamphetamine, and phenylephrine. Visual fields are tested in an infant by advancing a brightly colored (red) object from behind the child's head through the peripheral field of vision and noting when the child first looks at the object. Suspension of the object by a string prevents the infant from focusing on the examiner's hand and arm.

OCULOMOTOR (3), TROCHLEAR (4), AND ABDUCENS NERVES (6).

The eye is moved by the extraocular muscles that are innervated by the oculomotor, trochlear, and abducens nerves. The oculomotor nerve innervates the superior, inferior, and medial rectus as well as the inferior oblique and the levator palpebrae superioris muscles. Complete paralysis of the oculomotor nerve causes ptosis, dilation of the pupil, displacement of the eye outward and downward, and impairment of adduction and elevation. The trochlear nerve supplies the superior oblique muscle, and isolated paralysis causes the eye to deviate upward and outward, often with an associated head tilt. The abducens nerve innervates the lateral rectus muscle so that its paralysis causes medial deviation of the eye and the inability to abduct beyond the midline. In an older child, the **red glass test** is used to assess extraocular palsies. A red glass is placed over one eye, and the patient is requested to follow a white light in all fields of direction. The child sees only one red/white light in the direction of normal muscle function but notes a separation of the red and white images that is greatest in the plane of action of the affected muscle. *Internuclear ophthalmoplegia* results from a lesion in the brainstem and consists of paralysis of medial rectus function of the adducting eye and nystagmus confined to the abducting eye. *Internal ophthalmoplegia* refers to a dilated pupil that is unreactive to light and accommodation but has normal extraocular function, and *external ophthalmoplegia* is associated with ptosis and paralysis of all eye muscles with preservation of the pupillary response. *Nystagmus* is an involuntary rapid movement of the eye that may be horizontal, vertical, rotatory, pendular, or mixed. Jerk nystagmus is used to describe a fast and slow phase. As a general rule, horizontal nystagmus occurs with an abnormality of the peripheral labyrinth or with a lesion of the vestibular system in the brainstem or cerebellum and as a consequence of drugs, particularly phenytoin. Vertical nystagmus is indicative of brainstem dysfunction.

Complete ocular movement may be demonstrated as early as 25 wk of gestation using the **doll's eye maneuver**. This technique is used to examine horizontal and vertical eye movements in an infant or an uncooperative or comatose patient. If the head is suddenly turned to the right, the eyes look to the left in a symmetric fashion. Horizontal eye movements in the opposite direction may then be evaluated if the head is turned to the left. Vertical movements may be assessed in a similar fashion by rapid flexion and extension of the head. Normal infants and children follow a toy or interesting object in all directions. The rapid on-off occlusion (“blinking light”) of a light source is a reliable test for visual following in uncooperative children. The examiner observes the completeness and flow of the eye movements and determines the presence or absence and the direction of nystagmus, diplopia, opsoclonus (chaotic, jerky oscillations of the eyes, often associated with neuroblastoma or viral infections), ocular bobbing, or other abnormal eye positions. Premature infants tend to have slightly disconjugate eyes at rest, with one eye horizontally displaced from the other by 1 or 2?mm. Skew deviation of the eyes (vertical displacement) is always abnormal and requires investigation. Strabismus is discussed in Chapter 614 .

TRIGEMINAL NERVE (5).

The sensory distribution of the face is divided into three areas: the ophthalmic area, the maxillary area, and the mandibular area. Each region may be tested by light touch and by pinprick, and may be compared with the opposite side. The corneal response is elicited by touching the cornea with a small pledget of cotton and by observing the eye closure response. Trigeminal nerve function in premature infants is best documented by facial grimacing from a pinprick (away from the eye) or by stimulating the nostril with a cotton tip. Motor function may be tested by examination of the masseters, pterygoid, and temporalis muscles during mastication as well as by evaluation of the jaw jerk.

FACIAL NERVE (7).

Decreased voluntary movement of the lower face with flattening of the nasolabial angle on the ipsilateral side indicates an upper motor neuron or supranuclear corticospinal lesion. A lower motor neuron lesion tends to involve upper and lower facial muscles equally. Facial nerve paralysis may be congenital or secondary to trauma, infection, intracranial tumor, hypertension, toxins, or myasthenia gravis. Taste for the anterior two thirds of the tongue may be tested in a cooperative child by placing a solution of saline or glucose on one side of the extended tongue. Normal children can identify the substance with little difficulty.

AUDITORY NERVE (8).

Screening for hearing loss is an important component of the neurologic examination, because a hearing deficit is not readily recognized by parents (see Chapter 627). Normal newborns pause briefly during sucking when a bell is presented, but after several stimuli the pauses cease as habituation occurs. Neurologically abnormal infants do not habituate. Normal hearing infants turn their head toward a bell, rattle, or crumpled paper and by 3 mo of age look in the direction of the sound source. Normally intelligent, hearing-impaired toddlers are visually alert and respond appropriately to physical stimuli. Temper tantrums and abnormal speech are common symptoms in a hearing-impaired child. Audiometry or brainstem–evoked potential testing is mandatory for any child suspected of having a hearing loss (see Chapter 627). The risk factors that indicate a need for testing during the first few months of life include a family history of deafness, prematurity, severe asphyxia, use of ototoxic drugs in the newborn period, hyperbilirubinemia, congenital anomalies of the head or neck, bacterial meningitis, and congenital infections due to rubella, toxoplasmosis, herpes, and cytomegalovirus. Parental concern is often a reliable indicator of hearing impairment and warrants a formal hearing assessment.

Vestibular function may be evaluated by the *caloric test*. Approximately 5?mL of ice water is delivered by syringe into the external auditory canal with the patient's head elevated 30 degrees from the horizontal position. In obtunded or comatose patients with an intact brainstem, there is prompt deviation of the eyes to the side of the stimulus. A much smaller quantity of ice water (0.5?mL) is used in alert, awake subjects. In normal subjects, introduction of ice water produces nystagmus with the quick component in the opposite direction to the stimulated labyrinth. No response implies severe dysfunction of the brainstem and medial longitudinal fasciculus. If the otoscopic examination reveals a ruptured tympanic membrane, the test should not be performed in that ear.

GLOSSOPHARYNGEAL NERVE (9).

This nerve supplies innervation to the stylopharyngeus muscle. An isolated lesion of the 9th cranial nerve is rare. The nerve is tested by observing the gag response to tactile stimulation of the posterior pharyngeal wall. Taste for the posterior one third of the tongue is provided by the sensory portion of the glossopharyngeal nerve.

VAGUS NERVE (10).

A unilateral injury of the vagus nerve produces weakness and asymmetry of the ipsilateral soft palate and a hoarse voice due to paralysis of a vocal cord. Bilateral lesions may produce respiratory distress as a result of vocal cord paralysis as well as nasal regurgitation of fluids, pooling of secretions,

and an immobile, low-lying soft palate. Isolated lesions of the vagus nerve may occur postoperatively after a thoracotomy due to separation of the recurrent laryngeal nerve, and these lesions are not uncommon during the neonatal period in children with the type II Chiari malformation. If a lesion involving the vagus nerve is suspected, visualization of the vocal cords is necessary. To test for a cough in a neonate/infant, the examiner applies gentle pressure to the trachea at the suprasternal notch.

ACCESSORY NERVE (11).

Paralysis and atrophy of the sternomastoid and trapezius muscles result from lesions of the accessory nerve. The sternomastoid muscle has two origins, sternal and clavicular, and is tested by forceful rotation of the head and neck against the examiner's hand. Motor neuron disease, myotonic dystrophy, and myasthenia gravis are the most common conditions producing weakness and atrophy of these muscles.

HYPOGLOSSAL NERVE (12).

The hypoglossal nerve innervates the tongue. Examination of the tongue includes an assessment of its motility, size, and shape and the presence of atrophy or fasciculations. Malfunction of the hypoglossal nucleus or nerve produces wasting, weakness, and fasciculations of the tongue. If the injury is bilateral, tongue protrusion is not possible and dysphagia may be present. Werdnig-Hoffmann disease (infantile spinal muscular atrophy, or SMA type 1) and congenital anomalies in the region of the foramen magnum are the principal causes of hypoglossal nerve involvement.

Motor Examination.

The motor examination includes an assessment of the integrity of the

musculoskeletal system and a search for abnormal movements that may indicate a disorder of the peripheral nervous system or the CNS. The components of the motor examination include testing of strength (power), muscle bulk, tone, posture, locomotion and motility, deep tendon reflexes, and the presence of primitive reflexes, when applicable.

STRENGTH.

Testing of muscle strength is relatively straightforward in cooperative children. It may begin by requesting that the child squeeze the examiner's fingers, flex and extend the wrist and elbow, and adduct and abduct the shoulder against resistance. Shoulder girdle muscle strength may be evaluated in a newborn or infant by supporting the child by the axillae. Patients with weakness are unable to support body weight and slip through the examiner's hands. Distal power can be tested in an infant by evaluating the palmar grasp; a child with weakness does not adequately grasp or shows abnormalities in the manipulation of objects. A normal 3-to 4-yr-old child cooperates in testing extension or flexion of the muscles of the foot, knee, and hip. Examination of the pelvic girdle and proximal lower extremity muscles is also performed by observing the child climb steps or stand up from a prone position. Weakness in these muscles causes the child to use the hands to “climb up” the legs in order to assume an upright position, a maneuver called *Gowers sign* (Fig. 584–2). Infants with diminished power in the lower extremities tend to have decreased spontaneous activity in the legs and refuse to support body weight when suspended by the axillae. It is important not only to assess individual muscle groups but also to carefully compare muscle power between the upper and lower extremities as well as the opposite extremities. Muscle power in a cooperative child is graded on a scale of 0–5 as follows: 0 = no contraction; 1 = flicker or trace of contraction; 2 = active movement, with gravity eliminated; 3 = active movement against gravity; 4 = active movement against gravity and resistance; 5 = normal power. Examination of muscle power should include the muscles of respiration. Observation of the action of the intercostal muscles, diaphragmatic movement, and the use of accessory muscles of respiration should be

Figure 584-2 Gowers sign. A boy with hip girdle weakness due to Duchenne muscular dystrophy.

documented. Finally, evaluation of power should include an assessment of muscle bulk and nutrition. Weakness may be associated with muscle atrophy and fasciculations. Because most infants have excess body fat, muscle fasciculations and atrophy are most commonly demonstrated in the denervated tongue in this age group.

TONE.

Muscle tone is tested by assessing the degree of resistance when an individual joint is moved passively. Tone undergoes considerable change and assumes different forms depending on age. A premature or newborn infant is relatively hypotonic compared with a child. Tone in this age group is tested by various maneuvers (see Chapter 86). When the upper extremity of a normal term infant is pulled gently across the chest, the elbow normally does not quite reach the midsternum (*scarf sign*). The elbow of a hypotonic infant extends beyond the midline with ease. Measurement of the popliteal angle is a useful method to document tone in the legs of a newborn. The examiner flexes the child's lower extremity on the abdomen and extends the knee. Normal term infants allow extension of the knee to approximately 80 degrees. Abnormalities of tone consist of spasticity, rigidity, and hypotonia.

Spasticity is characterized by an initial resistance to passive movement, followed by a sudden release called the **clasp-knife** phenomenon. Spasticity is most apparent in the upper extremity flexors and lower extremity extensor muscles. It is associated with brisk tendon reflexes and an extensor plantar reflex, clonus, diminished active movements, and disuse atrophy. *Clonus* may be demonstrated in the lower extremity by sudden dorsiflexion of the foot with the knee partially flexed. Whereas sustained clonus is always abnormal, 5–10 beats in a newborn is a normal finding unless the clonus is asymmetric. Spasticity results from a lesion that involves upper motor neuron tracts and may be unilateral or bilateral. *Rigidity*, the result of a basal ganglia lesion, is characterized by constant resistance to passive movement of both extensor and flexor muscles. As the extremity is undergoing passive movement, a typical **cogwheel** (caused by superimposition of an extrapyramidal tremor on rigidity) sensation may be evident. The rigidity persists with repetitive passive extension and flexion of a joint and does not give way or release, such as with spasticity. Children with spastic lower extremities drag the legs while crawling (commando style) or walk on tiptoes. Patients with marked spasticity or rigidity develop a posture of *opisthotonos*, in which the head and the heels are bent backward and the body bowed forward (Fig. 584–3). *Decerebrate* rigidity is characterized by marked extension of the extremities resulting from dysfunction or injury to the brainstem at the level of the superior colliculi. *Hypotonia* refers to abnormally diminished tone and is the most common abnormality

Figure 584-3 Opisthotonus in a brain-injured infant.

of tone in neurologically compromised premature or full-term neonates. Demonstration of hypotonia may reflect pathology of the cerebral hemispheres, cerebellum, spinal cord, anterior horn cell, peripheral nerve, myoneural junction, or muscle. An unusual position or posture in an infant is a reflection of abnormal tone. A hypotonic infant is *floppy* and may have difficulty in maintaining head support or a straight back while sitting. Such infants may assume a **frog-leg posture** in the supine position. Premature infants of 28 wk of gestation tend to extend all extremities at rest, but by 32 wk there is evidence of flexion, particularly in the lower extremities. A normal full-term infant's posture is characterized by flexion of all extremities.

MOTILITY AND LOCOMOTION.

Premature infants of less than 32 wk of gestation display random, slow, writhing movements interspersed with rapid, myoclonic-like activity of the extremities. Beyond 32 wk, the motor activity is primarily flexor. Observation of crawling, walking, or running may uncover movement disorders, most of which are likely to be apparent during motion and to disappear with rest or sleep. *Ataxia* refers to incoordination of movement or a disturbance of balance. It may be primarily truncal or may be limited to the extremities. Truncal ataxia is characterized by unsteadiness during sitting or

standing and results primarily from involvement of the cerebellar vermis. Abnormalities of the cerebellar hemispheres characteristically cause intention tremor unaffected by visual attention. Ataxia may be demonstrated by the finger-to-nose and heel-to-shin tests, heel-to-toe or tandem walking, and, in infants by observation of reaching for or playing with toys. Additional abnormalities associated with cerebellar lesions include dysmetria (errors in measuring distances), rebound (inability to inhibit a muscular action, such as when the examiner suddenly releases the flexed arm and the patient inadvertently strikes the face), and disdiadochokinesia (diminished performance of rapid alternating movements). Hypotonia, dysarthria, nystagmus, and decreased deep tendon reflexes are common features of cerebellar abnormalities. Sensory ataxia is found with diseases of the spinal cord and peripheral nerves. In these disorders, the **Romberg sign** is positive (patient is unsteady with eyes closed but not open), and there are often related sensory findings including abnormalities in joint position and vibration sense.

Chorea is characterized by involuntary movements of the major joints, trunk, and the face that are rapid and jerky. Affected children are incapable of extending their arms without producing abnormal movements. They have a tendency to pronate the arms when held above the head. The hand grip contracts and relaxes (**milkmaid sign**), the speech is explosive and inarticulate, the deep tendon reflexes of the knee are "hung up," and patients may have difficulty in maintaining protrusion of the tongue. *Athetosis* is a slow, writhing movement that is often associated with abnormalities of muscle tone. It is most prominent in the distal extremities and is enhanced by voluntary activity or emotional upset. Speech and swallowing may be affected. Chorea and athetosis are the result of basal ganglia lesions and are difficult to separate clinically. Both may be prominent in the same patient. *Dystonia* is an involuntary, slow, twisting movement that primarily involves the proximal muscles of the extremities, trunk, and neck.

DEEP TENDON REFLEXES AND THE PLANTAR RESPONSE.

The deep tendon reflexes are readily elicited in most infants and children. In premature and term infants, the biceps, knee, and ankle jerks are the most reliable deep tendon reflexes. They are graded from 0 (absent) to 4 (markedly hyperactive), with 2 being normal. The ankle reflex is difficult to obtain by percussing the Achilles tendon in this age group. Gentle dorsiflexion of the foot and tapping the plantar surface with the reflex hammer usually elicits a response. The knee jerk in an infant may produce a crossed adductor response (tapping

the patellar tendon in one leg causes contraction in the opposite extremity), which, if present, does not become abnormal until 6–7 mo of age. The deep tendon reflexes are absent or decreased in primary disorders of the muscle (myopathy), nerve (neuropathy), and myoneural junction and in abnormalities of the cerebellum. They are characteristically increased in upper motor neuron lesions. Asymmetry of deep tendon reflexes suggests a lateralizing lesion. The plantar response is obtained by stimulation of the external portion of the sole of the foot, beginning at the heel and extending to the base of the toes. Firm pressure from the examiner's thumb is a useful method for eliciting the response. The *Babinski reflex* is characterized by extension of the great toe and by fanning of the remaining toes. Too vigorous stimulation may produce withdrawal, which may be misinterpreted as a Babinski response. Most newborn infants show an initial flexion of the great toe on plantar stimulation. As with adults, asymmetry of the plantar response between extremities is a useful lateralizing sign in infants and children.

PRIMITIVE REFLEXES.

Primitive reflexes appear and disappear in sequence during specific periods of development (Table 584–2). Their absence or persistence beyond a given time frame signifies dysfunction of the CNS. Some primitive reflexes, such as the snout or *rooting reflex*, reappear during old age or with specific degenerative diseases involving the cerebral cortex. Although many primitive reflexes have been described, the Moro, grasp, tonic neck, and parachute reflexes are the most important. The *Moro reflex* is obtained by placing the infant in a semi-upright position. The head is momentarily allowed to fall backward, with immediate resupport by the examiner's hand. The child symmetrically abducts and extends the arms and flexes the thumbs, followed by flexion and adduction of the upper extremities. An asymmetric response may signify a fractured clavicle, brachial plexus injury, or a hemiparesis. Absence of the Moro reflex in a term newborn is ominous, suggesting significant dysfunction of the CNS. The *grasp* response is elicited by placing a finger or object in the open palm of each hand. Normal infants grasp the object, and with attempted removal, the grip is reinforced. The *tonic neck* reflex is produced by manually turning the head to one side while supine. Extension of the arm occurs on that side of the body corresponding to the direction of the face, while flexion develops in the contralateral extremities. An obligatory tonic neck response, by which the infant remains "locked" in the fencer's position, is always abnormal and implies a CNS disorder. The *parachute reflex* is demonstrated by suspending the child by the trunk and by suddenly producing forward flexion as if the child were to fall. The child spontaneously extends the upper extremities as a protective mechanism. The parachute reflex appears before the onset of walking.

Sensory Examination.

Sensory examination is difficult to perform in an infant or uncooperative child. Furthermore, the understanding child soon tires of the examination because it requires considerable attention to repetitious and uninteresting tasks. The more this part of the neurologic examination can be made to simulate a game, the greater is the likelihood that a child will cooperate. Fortunately, disorders involving the sensory system are less common in the pediatric population than among adults; thus, this component of the neurologic assessment is less important for infants and children than for adolescents and adults.

TABLE 584-2 -- **Timing of Selected Primitive Reflexes**

Reflex	Onset	Fully Developed	Duration
Palmar grasp	28 wk	32 wk	2–3 mo
Rooting	32 wk	36 wk	Less prominent after 1 mo
Moro	28–32 wk	37 wk	5–6 mo
Tonic neck	35 wk	1 mo	6–7 mo

Parachute	7–8 mo	10–11 mo	Remains throughout life

While the infant is distracted by a parent or an interesting toy, the examiner touches the patient with a piece of cotton or a fragment of a tongue depressor. Normal children indicate an awareness of the stimulus by pausing during play, withdrawing the extremity, crying, or looking at and touching the stimulated area. Unfortunately, a child quickly loses patience and soon begins to disregard the examiner. It is critical, therefore, that the area in question is tested efficiently and, if necessary, re-examined at an appropriate time.

Identification of a sensory level in association with a *spinal cord lesion* can be very difficult in an infant. Observation may suggest a difference in color, temperature, or perspiration, with the skin cooler and dry below the spinal cord level. Touching the skin lightly above the level evokes a response that is usually in the form of a squirming movement or physical withdrawal. The superficial abdominal reflexes may be absent. A child with a spinal cord lesion may have evidence of rectal sphincter incontinence that is manifested by a patulous anus, by the absence of contraction of the sphincter when the skin in the anal region is stimulated with a sharp object (anal wink), and by a lack of contraction of the anal sphincter during the rectal examination. In boys, the presence of the cremasteric reflex is also a valuable finding. Children 4–5 yr of age are capable of detailed sensory testing, including joint position, vibration, temperature, stereognosis, two-point discrimination, double simultaneous extinction, light touch, and pain. The success of the sensory examination depends on the ingenuity and the patience of the examiner.

Gait and Station.

Observation of a child's gait is an important aspect of a neurologic examination. The *spastic gait* is characterized by stiffness and by stepping like a tin soldier. Spastic children may walk on tiptoes because of tightness or contractures of the Achilles tendons. *Hemiparesis* is associated with a decreased arm swing on the affected side and a lateral circular motion of the leg (*circumduction gait*). Extrapyramidal movements, such as dystonia or chorea, may become apparent while the child is walking or running. Cerebellar ataxia produces a broad-based unsteady gait, and if severe, the child requires support to prevent falling. Heel-to-toe or tandem walking is performed poorly in patients with abnormalities of the cerebellum. A *waddling gait* results from weakness of the proximal hip girdle. Affected children often develop a compensatory lordosis and have difficulty in climbing stairs. Weakness or hypotonia of the lower extremities may result in genu recurvatum and flat feet, which causes a clumsy, tentative gait. *Scoliosis* may cause an abnormal gait and can result from disorders of muscle and spinal cord.

GENERAL EXAMINATION

Physical examination of other organ systems is an essential component of a neurologic examination. For example, cutaneous lesions suggest a neurocutaneous syndrome (see Chapter 589); hepatosplenomegaly suggests inborn errors of metabolism, storage diseases, HIV, or malignancy; and dysmorphic features suggest various syndromes (see Chapter 97). Heart murmurs raise the possibility of rheumatic fever (chorea), tuberous sclerosis (cardiac rhabdomyoma), cerebral abscess or thrombosis (cyanotic heart disease), or cerebral vascular occlusion (endocarditis).

Soft Neurologic Signs.

These signs should be interpreted cautiously because they are present in normal children during various stages of neurodevelopment. A soft neurologic sign may be defined as a particular form of deviant performance on a motor or sensory test in the neurologic examination that is abnormal for a particular age. Testing for the presence of soft neurologic signs involves the observation of a series of timed motor tasks and a comparison of the quality and the precision of the patient's movement with normal controls of similar age and sex.

The tests include repetitive and successive finger movements, hand pats, arm pronation-supination movements, foot taps, hopping, and tandem walking. There is considerable variation in the expression of these signs, depending on age, sex, and maturation of the nervous system. For example, minimal choreoathetoid movements in the fingers of the extended arms are normal at 4 yr of age but disappear by 7 or 8 yr of age. Neurodevelopment of girls is more accelerated than that of boys for many motor tasks, including hopping, skipping, and fine balance maneuvers. Although intellectually normal children may demonstrate a soft neurologic sign, the finding of two or more persistent soft signs correlates significantly with neurologic dysfunction, including attention deficit disorder, learning disorders, and cerebral palsy. Because specific soft signs lack association with a particular disability and can occur in a normal child, it is unwise to label a child who shows several soft neurologic signs. It is more appropriate to monitor such a patient closely and to ensure that a developmental disability has been precluded.

SPECIAL DIAGNOSTIC PROCEDURES

Lumbar Puncture and Cerebrospinal Fluid Examination.

Examination of the cerebrospinal fluid (CSF) is essential in confirming the diagnosis of meningitis, encephalitis, and subarachnoid hemorrhage and is often helpful in evaluating demyelinating, degenerative, and collagen vascular diseases and the presence of tumor cells within the subarachnoid space. Preparation of a patient is important in order to successfully complete the procedure. An experienced assistant has a vital role in positioning, restraining, and comforting the patient. The skin is thoroughly prepared with a cleansing agent, and the patient is placed in the lateral recumbent position. The physician should be gowned and gloved; the patient should be draped. The neck and legs of the patient are flexed by an assistant to enlarge the intervertebral spaces. The ideal interspace for lumbar puncture (LP) is L3-L4 or L4-L5, which is determined by drawing an imaginary horizontal line from one anterior superior spine of the ilium to the other. The skin and underlying tissue are anesthetized with a local anesthetic or by placing on the skin 30?min before the procedure a patch that contains a eutectic mixture of local anesthetics including lidocaine and prilocaine (EMLA). A 22-gauge, 1-to 2-in, sharp, beveled spinal needle with a properly fitting stylet is introduced into the midsagittal plane directed slightly in the cephalic direction. The stylet is removed frequently as the needle is slowly

advanced to determine whether CSF is present. A pop is felt as the needle penetrates the dura and enters the subarachnoid space. A manometer and a three-way stopcock may be attached to obtain an opening pressure. The opening pressure in the recumbent and relaxed position averages 100?mm of fluid; the range in the flexed lateral decubitus position is 60–180?mm of fluid. The most common cause of an elevated opening pressure is a crying, uncooperative, and struggling patient. The pressure is recorded most reliably with a child positioned comfortably with the head and the legs extended. Sick neonates may be placed in the upright position for a spinal tap, because decreased ventilation and perfusion abnormalities leading to respiratory arrest are more common in the recumbent position in this age group.

Contraindications for performing an LP include: (1) elevated ICP owing to a suspected mass lesion of the brain or spinal cord, (2) symptoms and signs of pending cerebral herniation in a child with probable meningitis, (3)critical illness (on rare occasions), (4) skin infection at the site of the LP, and (5) thrombocytopenia.

In the first instance, transtentorial herniation or herniation of the cerebellar tonsils may develop after the procedure. Inspection of the eyegrounds for the presence of papilledema is mandatory before proceeding with an LP.

In the second instance, symptoms and signs include decerebrate or decorticate posture, a generalized tonic seizure, abnormalities of pupil size and reaction, with absence of the oculocephalic response and fixed oculomotor deviation of the eyes. Pending herniation is also associated with respiratory abnormalities, including hyperventilation, Cheyne-Stokes respiration, ataxic breathing, apnea, and respiratory arrest. These children must be treated immediately with appropriate intravenous antibiotics and transported to a critical care unit for stabilization and imaging studies before an LP is contemplated. LP is the primary diagnostic procedure in children with suspected bacterial meningitis in the absence of overwhelming sepsis or shock, or symptoms and signs of brain herniation. Because the clinical status of children with untreated bacterial meningitis may rapidly deteriorate, deferral of the LP and initiation of appropriate antibiotic therapy while awaiting the results of a CT scan could be the determining factor between recovery or severe complications and death.

In the third case, *on rare occasions*, an LP is temporarily withheld from a critically ill, moribund patient because the procedure may produce cardiorespiratory arrest. In this situation, blood cultures are drawn, antibiotics and supportive care are administered, and when the patient is stabilized, an LP may be accomplished safely under more controlled circumstances.

In the fourth instance, if examination of the CSF is urgent in a patient with skin infection at the site of the LP, a ventricular or cisterna magna tap performed by a skilled physician is indicated.

In the fifth instance, thrombocytopenia, with a platelet count less than 20×10^9 /L, may cause uncontrolled bleeding in the subarachnoid or subdural space.

Normal CSF is the color of water. Cloudy CSF results from an elevated white blood cell (WBC) or red blood cell (RBC) count. Normal CSF contains up to 5/mm^3 WBCs, and a newborn may have as many as 15/mm^3 . Polymorphonuclear (PMN) cells are always abnormal in a child, but 1–2/mm^3 may be present in a normal neonate. The presence of PMN cells raises suspicion of a pathologic process. An elevated PMN count suggests bacterial meningitis or the early phase of an aseptic meningitis (see Chapter 594). CSF lymphocytosis indicates aseptic, tuberculous, or fungal meningitis; demyelinating diseases; brain or spinal cord tumor; immunologic disorders including collagen vascular diseases; and chemical irritation (e.g., postmyelogram, intrathecal methotrexate).

A Gram stain of the CSF is essential in the investigation of suspected bacterial meningitis; an acid-fast stain or India ink preparation is used if tuberculous or fungal meningitis is a possibility. The fluid is placed on appropriate culture media based on the clinical findings and on the CSF analysis.

Normal CSF contains no RBCs. The presence of RBCs indicates a traumatic tap or a subarachnoid hemorrhage. Bloody CSF should be centrifuged immediately. The supernatant of a bloody tap is clear, but it is xanthochromic in the presence of a subarachnoid hemorrhage. Progressive clearing of bloody CSF is noted during collection of the fluid in the case of a traumatic tap. The presence of crenated RBCs does not differentiate a traumatic tap from a subarachnoid hemorrhage. In addition to a subarachnoid hemorrhage, xanthochromia may result from hyperbilirubinemia, carotenemia, and a markedly elevated CSF protein.

The normal *CSF protein* ranges from 10–40?mg/dL in a child to as high as 120?mg/dL in a neonate. The CSF protein falls to the normal childhood range by 3 mo of age. The CSF protein may be elevated in many processes, including infectious, immunologic, vascular, and degenerative diseases as well as tumors of the brain and spinal cord. The CSF protein is increased after a bloody tap by approximately 1?mg/dL for every 1,000?mm^3 . Elevation of CSF immunoglobulin G (IgG), which normally represents approximately 10% of the total protein, is observed in subacute sclerosing panencephalitis, postinfectious encephalomyelitis, and in some cases of multiple sclerosis. If the diagnosis of multiple sclerosis is suspected, the CSF should be tested for the presence of oligoclonal bands.

The *CSF glucose* content is about 60% of the blood glucose in a healthy child. To prevent a spuriously elevated blood/CSF glucose ratio in a case of suspected meningitis, it is advisable to collect the blood glucose before the LP when the child is relatively calm. Hypoglycorrhachia is found in association with diffuse meningeal disease, particularly bacterial and tuberculous meningitis. In addition, widespread neoplastic involvement of the meninges, subarachnoid hemorrhage, fungal meningitis, and, on occasion, aseptic meningitis can produce a low CSF glucose level.

The CSF may also be examined for specific *antigens* (e.g., latex agglutination for suspected meningitis) and in investigation of a series of metabolic diseases (e.g., lactate, amino acids, endolase determination).

Subdural Tap.

This procedure may be indicated to establish the diagnosis of a subdural effusion or hematoma. A blunt, short-beveled 20-gauge needle and stylet are used for the procedure. The subdural space is approached at the lateral border of the anterior fontanel or along the upper margin of the coronal suture at least 2–3?cm from the midline to prevent injury to the underlying sagittal sinus. After adequate cleansing and preparation of the skull, including shaving of the hair from the operative site, the patient is placed in the supine position and is firmly held by an attendant. After a local anesthetic, the needle and stylet are slowly advanced through the skin and underlying tissue with a z-like movement until the dura is entered with a sudden popping sensation. Considerable care is taken to prevent advancement of the needle into the cerebral cortex, which in an infant is approximately 1.5?cm from the skin surface. A hemostat attached approximately 5–7?mm from the beveled end of the needle should provide an adequate safeguard. The subdural fluid, which may squirt out under pressure, is collected and sent for protein analysis, cell count, and culture. The color of the fluid may be xanthochromic, bright red, or oily brown (depending on the age of the subdural collections). Bilateral subdural taps may be indicated, because subdural collections are bilateral in most cases. The amount of fluid removed with each tap should be limited to a total of 15–20?mL from each side in order to prevent rebleeding from a sudden shift of the intracranial contents. At the termination of the procedure, a sterile dressing is applied, and the child is placed in a sitting position that tends to prevent leakage of fluid from the puncture site. (See Chapter 594 for a discussion of subdural fluid associated with meningitis.)

Ventricular Tap.

A ventricular tap is used for the removal of CSF in the management of life-threatening increased ICP associated with hydrocephalus, when conservative measures have failed. The procedure should not be undertaken by a pediatrician except when the patient's life is in jeopardy and a neurosurgeon is not available. For an infant, the procedure is similar to a subdural tap. A 20-gauge ventricular needle with a stylet is placed in the lateral border of the anterior fontanel and is directed toward the inner canthus of the ipsilateral eye. The needle is advanced slowly, and the stylet is removed frequently to determine the presence of CSF. The ventricle is usually encountered about 4?cm from the skin surface.

Neuroradiologic Procedures.

A *skull roentgenogram* is occasionally a useful diagnostic procedure. It may demonstrate fractures, intracranial calcification, craniosynostosis, congenital anomalies, or bony defects and evidence of increased ICP. Acute increased ICP is characterized by separation of the sutures, whereas erosion of the posterior clinoid processes, enlargement of the sella turcica, and an increase in convolutional markings indicate long-standing intracranial hypertension.

CT scanning is an important diagnostic procedure for emergencies and for less emergent disorders. CT scanning is a noninvasive procedure that uses conventional x-ray techniques. Sedation is usually required for infants and young children, because a lack of head movement is essential during the study. Pentobarbital, 4?mg/kg IM 30?min before the CT scan, with a supplementary dose of 2?mg/kg IM 1–½?hr later if necessary, is usually effective. Chloral hydrate, 50–75?mg/kg PO 45?min before the procedure, is an alternative method of sedation. CT scanning is useful in demonstrating congenital malformations of the brain, including hydrocephalus and porencephalic cysts, subdural collections, cerebral atrophy, intracranial calcification, intracerebral hematoma, brain tumors and areas of cerebral edema, infarction, and demyelination (Table 584–3). Intravenous injection of radiographic contrast medium enhances areas of increased vascular permeability due to abnormalities of the blood-brain barrier and highlights abnormal collections of blood vessels in an arteriovenous malformation.

MRI is a noninvasive procedure and is especially well suited for the study of neoplasms, cerebral edema, demyelination, degenerative diseases, and congenital anomalies, particularly of the posterior fossa and spinal cord (see Table 584–3). MRI is capable of detecting small plaques in patients with multiple sclerosis and areas of localized gliosis in children with uncontrolled

TABLE 584-3 -- **Preferred Imaging Procedures in Neurologic Diseases**

Neurologic Disease	Imaging Procedure
Cerebral or cerebellar ischemic infarction	CT in the first 12–24 hr; MRI after 12–24 hr (diffusion-weighted and perfusion-weighted MRI augments the findings, especially in the first 24 hr, and even before 8 hr)
Cerebral or cerebellar hemorrhage	CT in the first 24 hr; MRI after 24 hr; MRI and endovascular angiography for suspected arteriovenous malformation
Transient ischemic attack	MRI to identify lacunar or other small lesions; ultrasound studies of the carotid arteries; magnetic resonance angiography
Arteriovenous malformation	CT for acute hemorrhage; MRI and endovascular angiography as early as possible
Cerebral aneurysm	CT for acute subarachnoid hemorrhage; CT angiography or endovascular angiography to identify the aneurysm; TCD to detect vasospasm
Brain tumor	MRI without and with injection of contrast material
Craniocerebral trauma	CT initially; MRI after initial assessment and treatment
Multiple sclerosis	MRI without and with injection of contrast material
Meningitis or encephalitis	CT without and with injection of contrast material initially; MRI after initial assessment and treatment
Cerebral or cerebellar abscess	CT without and with injection of contrast material for initial diagnosis or, if stable, MRI instead of CT; MRI without and with injection of contrast material subsequently
Granuloma	MRI without and with injection of contrast material
Dementia	MRI; PET; SPECT
Movement disorders	MRI; PET

Neonatal and development disorders	Ultrasonography in unstable premature neonates; otherwise MRI
Epilepsy	MRI; PET; SPECT
Headache	CT in patients suspected of having structural disorders

PET = positron-emission tomography; SPECT = single-photon-emission computed tomography;TCD = transcranial Doppler ultrasonography. From Gilman S: Imaging the brain. N Engl J Med *1998; 338:812.*

seizures. MRI is routinely used in the evaluation of children who are potential candidates for epilepsy surgery. Intracerebral calcifications are not detected by MRI. The contrast agent, gadolinium-DTPA, is useful during MRI, especially to highlight lesions associated with a disrupted blood-brain barrier. Functional MRI (fMRI) is a noninvasive technique for detecting and mapping with high resolution the hemodynamic changes produced by localized brain activity during specific cognitive and/or sensorimotor function. It is useful for presurgical localization of critical brain functions (and is very promising as a tool for investigating the development and plasticity of these functions).

Radionuclide brain scan uses a radioactive material such as ^{99} Tc, which concentrates in regions where the blood-brain barrier has been disrupted. It is useful in the investigation of herpes encephalitis and cerebral abscess. *Positron-emission tomography* (PET) provides unique information on brain metabolism and perfusion by measuring blood flow, oxygen uptake, and glucose consumption. PET is an expensive technique that has been used primarily in adults, but it is increasingly used in many pediatric centers, particularly those with active epilepsy surgery programs. *Single-photon-emission computerized tomography* (SPECT), using ^{99m} Tc hexamethyl propylenamine oxime (Tc 99m-HMPAO) is a sensitive and inexpensive technique to study regional cerebral blood flow. SPECT is particularly useful in investigating cerebral vascular disease in children (systemic lupus erythematosus), as well as herpes encephalitis, and for localization of focal epileptiform discharges and recurrent brain tumors. *Cerebral angiography* is reserved for the study of vascular disorders. The procedure requires a general anesthetic in most children. Cerebral angiography, using subtraction techniques, is particularly useful for the delineation of arteriovenous malformations, aneurysms, arterial occlusions, and venous thrombosis. In most cases, a four-vessel study (internal carotids and vertebral arteries) is accomplished. *MRA* (angiography) may reduce the need for contrast invasive angiography. *Cranial ultrasonography* for the detection of periventricular leukomalacia, intracranial hemorrhage, hydrocephalus, and intracranial tumors, is limited to infants with a patent fontanel. The procedure is used intraoperatively in older children for placing shunts, locating small tumors, and directing needle biopsies. *Myelography* was used in the past for demonstrating congenital anomalies, tumors, and vascular malformations of the spinal cord. MRI is superior in most cases to contrast myelography and is not associated with arachnoiditis, which occasionally complicates injection of contrast material into the subarachnoid space.

Electroencephalography.

An *electroencephalogram* (EEG) provides a continuous recording of electrical activity between reference electrodes placed on the scalp. Although the genesis of the electrical activity is not certain, it likely originates from postsynaptic potentials in the dendrites of cortical neurons. Even with amplification of the electrical activity, not all potentials are recorded because there is a buffering effect of the scalp, muscles, bone, vessels, and subarachnoid fluid. The EEG waves are classified according to their frequency as delta (1–3/sec), theta (4–7/sec), alpha (8–12/sec), and beta (13–20/sec). These waves are altered by many factors, including age, state of alertness, eye closure, drugs, and disease states. High-voltage slow and sharp waves (K complexes) and sleep spindles (regular 12–14/sec waves) confined to the central regions occur during sleep in a normal EEG. Abnormalities of waveform include spikes and slow waves. Spikes are characteristically paroxysmal, sharp, and of high voltage followed by a slow wave. Spikes and slow waves are associated with epilepsy, but some normal patients may have this EEG finding. Focal spikes are often associated with irritative lesions, including cysts, slow-growing tumors, and glial scar tissue. Epileptiform activity may be enhanced by activation procedures, including hyperventilation, photic stimulation, and sleep deprivation. Slow waves may be focal, in which case a circumscribed lesion such as a hematoma, tumor, infarction, or a localized infectious process may be considered; generalized slow waves suggest a metabolic, inflammatory, or more widespread process.

EEG/polygraphic/video monitoring provides precise characterization of seizure types, which allows for specific medical or surgical management. In addition, the physician is more accurately able to differentiate epileptic seizures from paroxysmal events that mimic epilepsy, including pseudoseizures. EEG/polygraphic/video monitoring provides for measurement of seizure discharges and for study of the efficacy of various therapeutic regimens. Finally, polygraphic/EEG with video monitoring simultaneously records physiologic and EEG changes; it is particularly useful in neonates in whom the characterization of seizures is difficult.

Magnetoencephalography (MEG) detects magnetic fields associated with the intracellular current flow within neurons. *Magnetic source imaging (MSI)* is an advanced neurophysiologic technique that combines MEG and MRI to measure the magnetic field generated by a series of neurons. MSI is particularly useful for the investigation of patients who may be candidates for epilepsy surgery.

Evoked Potentials.

An evoked potential is an electrical response that follows stimulation of the CNS by a specific stimulus of the visual, auditory, or sensory system. Clinical application of evoked potentials in infants and children has increased dramatically during the past decade. Stimulation of the visual system by a flash or patterned stimulus, such as a black-and-white checkerboard, produces *visual-evoked potentials* (VEPs), which are recorded over the occiput and averaged in a computer. Abnormal VEPs result from lesions involving the visual system from the retina to the visual cortex. Neurodegenerative diseases, such as Tay-Sachs, Krabbe, Pelizaeus-Merzbacher disease, and neuronal ceroid lipofuscinoses, show characteristic VEP abnormalities.

Lesions of the optic nerve and chiasm also produce abnormalities in the VEP response. The VEP, using patterned stimuli, is useful particularly in assessing visual function in at-risk neonates. Flash VEPs are also very useful in predicting outcome in term infants after asphyxia. *Brainstem auditory-evoked potentials* (BAEPs) may be used to objectively measure hearing acuity, particularly in a neonate or uncooperative child when routine hearing assessment techniques have failed. BAEPs are abnormal in many neurodegenerative diseases in children and are an important tool in evaluating patients with suspected tumors of the cerebellopontine angle. BAEPs are helpful in the assessment of brainstem function in comatose patients, because the waveforms are unaffected by drugs or by the level of consciousness. They are not accurate in predicting neurologic recovery and outcome. *Somatosensory-evoked potentials* (SSEPs) are obtained by stimulating a peripheral nerve (peroneal, median) and by recording the electrical response over the cervical region and contralateral parietal somatosensory cortex. The SSEP determines the functional integrity of the dorsal column-medial-lemniscal system and is useful in monitoring spinal cord function during operative procedures, such as scoliosis, the repair of coarctation of the aorta, and myelomeningocele. SSEPs are abnormal in many neurodegenerative disorders in children and are the most accurate evoked potential in the assessment of neurologic outcome following a severe CNS insult.

Chapter 585 - Congenital Anomalies of the Central Nervous System

Michael V. Johnston
Stephen Kinsman

585.1 Neural Tube Defects (Dysraphism)

Neural tube defects account for most congenital anomalies of the central nervous system (CNS) and result from failure of the neural tube to close spontaneously between the 3rd and 4th wk of in utero development. Although the precise cause of neural tube defects remains unknown, evidence suggests that many factors, including radiation, drugs, malnutrition, chemicals, and genetic determinants (mutations in folate-responsive or folate-dependent pathways), may adversely affect normal development of the CNS from the time of conception. In some cases, an abnormal maternal nutritional state or exposure to radiation before conception may increase the likelihood of a CNS congenital malformation. The major neural tube defects include spina bifida occulta, meningocele, myelomeningocele, encephalocele, anencephaly, dermal sinus, tethered cord, syringomyelia, diastematomyelia, and lipoma involving the conus medullaris.

The human nervous system originates from the primitive ectoderm that also develops into the epidermis. The ectoderm, endoderm, and mesoderm form the three primary germ layers that are developed by the 3rd wk. The endoderm, particularly the notochordal plate and the intraembryonic mesoderm, induces the overlying ectoderm to develop the neural plate during the 3rd wk of development (Fig. 585–1*A*). Failure of normal induction is responsible for most of the neural tube defects. Rapid growth of cells within the neural plate causes further invagination of the neural groove and differentiation of a conglomerate of cells, the neural crest, which migrate laterally on the surface of the neural tube (see Fig. 585–1*B*). The notochordal plate becomes the centrally placed notochord, which acts as a foundation around which the vertebral column ultimately develops. With formation of the vertebral column, the notochord undergoes involution and becomes the nucleus pulposus of the intervertebral disks. The neural crest cells differentiate to form the peripheral nervous system, including the spinal and autonomic ganglia as well as the ganglia of cranial nerves V, VII, VIII, IX, and X. In addition, the neural crest forms the leptomeninges, as well as Schwann cells, which are responsible for myelinization of the peripheral nervous system. The dura is believed to arise from the paraxial mesoderm.

During the 3rd wk of embryonic development, invagination of the neural groove is completed and the neural tube is formed by separation from the overlying surface ectoderm (see Fig. 585–1*C*). Initial closure of the neural tube is accomplished in the area corresponding to the future junction of the spinal cord and medulla and moves rapidly both caudally and rostrally. For a brief period, the neural tube is open at both ends, and the neural canal communicates freely with the amniotic cavity (see Fig. 585–1*D*). Failure of closure of the neural tube allows excretion of fetal substances (e.g., a-fetoprotein [AFP], acetylcholinesterase) into the amniotic fluid, serving as biochemical markers for a neural tube defect. Prenatal screening of maternal serum for AFP during 16–18 wk of gestation is an effective method for identifying pregnancies at risk for fetuses with neural tube defects in utero. Normally, the rostral end of the neural tube closes on the 23rd day and the caudal neuropore closes by a process of secondary neurulation by the 27th day of development, before the time that many women realize they are pregnant.

585.2 Spina Bifida Occulta

This common anomaly consists of a midline defect of the vertebral bodies without protrusion of the spinal cord or meninges. Most individuals are asymptomatic and lack neurologic signs, and the condition is usually of no consequence. In some cases, patches of hair, a lipoma, discoloration of the skin, or a dermal sinus in the midline of the low back signifies an underlying malformation of the spinal cord. A spine roentgenogram shows a defect in closure of the posterior vertebral arches and laminae, typically involving L5 and S1. There is no abnormality of the meninges, spinal cord, or nerve roots. Spina bifida occulta is occasionally associated with more significant developmental abnormalities of the spinal cord, including syringomyelia, diastematomyelia, and a tethered cord. A *dermoid sinus* usually forms a small skin opening, which leads into a narrow duct, sometimes indicated by protruding hairs, a hairy patch, or a vascular nevus. Dermoid sinuses occur in the midline at the site of occurrence of meningoceles or encephaloceles, that is, the lumbosacral region or occiput. Dermoid sinus tracts may pass through the dura, acting as a conduit for the spread of infection. Recurrent meningitis of occult origin should prompt careful examination for a small sinus tract in the posterior midline region, including the back of the head.

585.3 Meningocele

A meningocele is formed when the meninges herniate through a defect in the posterior vertebral arches. The spinal cord is usually normal and assumes a normal position in the spinal canal, although there may be tethering, syringomyelia, or diastematomyelia. A fluctuant midline mass that may transilluminate occurs along the vertebral column, usually in the low back. Most meningoceles are well covered with skin and pose no threat to the patient. Careful neurologic examination is mandatory. Asymptomatic children with normal neurologic findings and full-thickness skin covering the meningocele may have surgery delayed. Before surgical correction of the defect, the patient must be thoroughly examined with the use of plain roentgenograms, ultrasonography, and MRI to determine the extent of neural tissue involvement, if any, and associated anomalies, including diastematomyelia, tethered spinal cord, and lipoma. Those patients with leaking cerebrospinal fluid (CSF) or a thin skin covering should undergo immediate surgical treatment to prevent meningitis. A CT scan of the head is recommended for children with a meningocele because of the association with hydrocephalus in some cases. An anterior meningocele projects into the pelvis through a defect in the sacrum. Symptoms of constipation and bladder dysfunction develop due to the increasing size of the lesion. Female patients may have associated anomalies of the genital tract, including a rectovaginal fistula and vaginal septa. Plain roentgenograms demonstrate a defect in the sacrum, and CT scanning or MRI outlines the extent of the meningocele.

585.4 Myelomeningocele

Myelomeningocele represents the most severe form of dysraphism involving the vertebral column and occurs with an incidence of approximately 1/4,000 live births.

Etiology.

The cause of myelomeningocele is unknown, but as with all neural tube closure defects, a genetic predisposition exists; the risk of recurrence after one affected child increases to 3–4% and increases to approximately 10% with two previous abnormal pregnancies. Nutritional and environmental factors undoubtedly have a role in the etiology of myelomeningocele. There is strong evidence that maternal periconceptional use of folic acid supplementation reduces the incidence of neural tube defects in pregnancies at risk by at least 50%. To be effective, folic acid supplementation should be initiated before conception and continued until at least the 12th wk of gestation when neurulation is complete. The U.S. Public Health Service has recommended that all women of childbearing age and who are capable of becoming pregnant take 0.4?mg of folic acid daily and that women who have previously had a pregnancy resulting in a neural tube defect be treated with 4?mg of folic acid daily, beginning 1 mo before the time the pregnancy is planned. The modern diet provides about half the daily requirement of folic acid. In order to increase folic acid intake, fortification of flour, pasta, rice, and cornmeal with 0.15?mg folic acid per 100?g was mandated in the United States and Canada in 1998. Unfortunately, the added folic acid will be insufficient to meet the minimal requirements to prevent neural tube defects. Therefore, informative educational programs remain essential for women planning a pregnancy. Certain drugs—including drugs that antagonize folic acid such as trimethoprim and the anticonvulsants carbamazepine, phenytoin, phenobarbital, and primidone—increase the risk of myelomeningocele. The anticonvulsant valproic acid causes neural tube defects in approximately 1–2% of pregnancies if the drug is administered during pregnancy. Some epilepsy clinicians recommend that all female patients of childbearing potential

who take anticonvulsant medications should also receive folic acid supplements.

Clinical Manifestations.

The condition produces dysfunction of many organs and structures, including the

skeleton, skin, and genitourinary tract, in addition to the peripheral nervous system and the CNS. A myelomeningocele may be located anywhere along the neuraxis, but the lumbosacral region accounts for at least 75% of the cases. The extent and degree of the neurologic deficit depend on the location of the myelomeningocele. A lesion in the low sacral region causes bowel and bladder incontinence associated with anesthesia in the perineal area but with no impairment of motor function. Newborns with a defect in the midlumbar region typically have a saclike cystic structure covered by a thin layer of partially epithelialized tissue (Fig. 585–2). Remnants of neural tissue are visible beneath the membrane, which may occasionally rupture and leak CSF. Examination of the infant shows a flaccid paralysis of the lower extremities, an absence of deep tendon reflexes, a lack of response to touch and pain, and a high incidence of postural abnormalities of the lower extremities (including clubfeet and subluxation of the hips). Constant urinary dribbling and a relaxed anal sphincter may be evident. Thus, a myelomeningocele in the midlumbar region tends to produce lower motor neuron signs due to abnormalities and disruption of the conus medullaris. Infants with myelomeningocele typically have an increasing neurologic deficit as the myelomeningocele extends higher into the thoracic region. However, patients with a myelomeningocele in the upper thoracic or the cervical region usually have a very minimal neurologic deficit and in most cases do not have hydrocephalus.

Hydrocephalus in association with a type II Chiari defect develops in at least 80% of patients with myelomeningocele. Generally, the lower the deformity in the neuraxis (e.g., sacrum), the less likely is the risk of hydrocephalus. Ventricular enlargement may be indolent and slow growing or may be rapid, causing a bulging anterior fontanel, dilated scalp veins, setting-sun appearance of the eyes, irritability, and vomiting associated with an increased head circumference. Not infrequently, infants with hydrocephalus and Chiari II malformation develop symptoms of hindbrain dysfunction, including difficulty feeding, choking, stridor, apnea, vocal cord paralysis, pooling of secretions, and spasticity of the upper extremities, which, if untreated, can lead to death. This *Chiari crisis* is due to downward herniation of the medulla and cerebellar tonsils through the foramen magnum.

Treatment.

Management and supervision of a child and family with a myelomeningocele require a *multidisciplinary team approach*, including surgeons, physicians, and therapists, with one individual (often a pediatrician) acting as the advocate and coordinator of the treatment program. The news that a newborn

Figure 585.4-2 A lumbar myelomeningocele is covered by a thin layer of skin.

child has a devastating condition such as myelomeningocele causes parents to feel considerable grief and anger. They need time to learn about the handicap and the associated complications and to reflect on the various procedures and treatment plans. The parents must be given the facts by a knowledgeable individual in an unhurried and nonthreatening setting. If possible, discussions with other parents of children with neural tube defects are helpful in resolving important questions and issues.

Surgery can be delayed for several days (except when there is a CSF leak) to allow the parents time to begin to adjust to the shock and to prepare for the multiple procedures and inevitable problems that lie ahead. Evaluation of other congenital anomalies and renal function can also be initiated before surgery. Most pediatric centers aggressively treat the majority of infants with myelomeningocele. After repair of a myelomeningocele, most infants require a shunting procedure for hydrocephalus. If symptoms or signs of hindbrain dysfunction appear, early surgical decompression of the medulla and cervical cord is indicated. Clubfeet may require casting, and dislocated hips may require operative procedures.

Careful evaluation and reassessment of the *genitourinary system* are some of the most important components of the management. Teaching the parents, and ultimately the patient, to regularly catheterize a neurogenic bladder is a crucial step in maintaining a low residual volume that prevents urinary tract infections and reflux leading to pyelonephritis and hydronephrosis. Periodic urine cultures and assessment of renal function, including serum electrolytes and creatinine as well as renal scans, intravenous pyelograms, and ultrasonography, are obtained according to the progress of the patient and the results of the physical examination. This approach to urinary tract management has greatly reduced the need for surgical diversionary procedures and has significantly decreased the morbidity and mortality associated with progressive renal disease in these patients. Some children can become continent with surgical implantation of an artificial urinary sphincter or bladder augmentation at a later age. Although *incontinence of fecal matter* is common and is socially unacceptable during the school years, it does not pose the same risks as urinary incontinence. Many children can be bowel-trained with a regimen of timed enemas or suppositories that allows evacuation at a predetermined time once or twice a day. Appendicostomy for antegrade enemas may also be helpful. Also see Chapter 20.4 .

Functional *ambulation* is the wish of each child and parent and may be possible, depending on the level of the lesion and on intact function of the iliopsoas muscles. Almost every child with a sacral or lumbosacral lesion obtains functional ambulation; approximately half the children with higher defects ambulate with the use of braces and canes.

Prognosis.

For a child who is born with a myelomeningocele and who is treated aggressively, the mortality rate is approximately 10–15%, and most deaths occur before age 4 yr. At least 70% of survivors have normal intelligence, but learning problems and seizure disorders are more common than in the general population. Previous episodes of meningitis or ventriculitis adversely affect the ultimate intelligence quotient. Because myelomeningocele is a chronic handicapping condition, periodic multidisciplinary follow-up is required for life.

585.5 Encephalocele

Two major forms of dysraphism affect the skull, resulting in protrusion of tissue through a bony midline defect, called *cranium bifidum*. A *cranial meningocele* consists of a CSF-filled meningeal sac only, and a *cranial encephalocele* contains the sac plus cerebral cortex, cerebellum, or portions of the brainstem. Microscopic examination of the neural tissue within an encephalocele often reveals abnormalities. The cranial defect occurs most commonly

in the occipital region at or below the inion, but in certain parts of the world frontal or nasofrontal encephaloceles are more prominent. These abnormalities are one tenth as common as neural tube closure defects involving the spine. The etiology is presumed to be similar to that for anencephaly and myelomeningocele, because examples of each have been reported in the same family.

Infants with a cranial encephalocele are at increased risk for developing hydrocephalus due to aqueduct stenosis, Chiari malformation, or the Dandy-Walker syndrome. Examination may show a small sac with a pedunculated stalk or a large cystlike structure that may exceed the size of the cranium. The lesion may be completely covered with skin, but areas of denuded skin can occur and require urgent surgical management. Transillumination of the sac may indicate the presence of neural tissue. A plain roentgenogram of the skull and cervical spine is indicated to define the anatomy of the vertebra. Ultrasonography is most helpful in determining the contents of the sac, obviating the need for a CT scan in most cases. Children with a cranial meningocele generally have a good prognosis, whereas patients with an encephalocele are at risk for visual problems, microcephaly, mental retardation, and seizures. Generally, children with neural tissue within the sac and associated hydrocephalus have the poorest prognosis. *Meckel-Gruber syndrome* is a rare autosomal recessive condition that is characterized by an occipital encephalocele, cleft lip or palate, microcephaly, microphthalmia, abnormal genitalia, polycystic kidneys, and polydactyly. Encephaloceles may be diagnosed in utero by determination of AFP levels and ultrasound measurement of the biparietal diameter.

585.6 Anencephaly

An anencephalic infant presents a distinctive appearance with a large defect of the calvarium, meninges, and scalp associated with a rudimentary brain, which results from failure of closure of the rostral neuropore. The primitive brain consists of portions of connective tissue, vessels, and neuroglia. The cerebral hemispheres and cerebellum are usually absent, and only a residue of the brainstem can be identified. The pituitary gland is hypoplastic, and the spinal cord pyramidal tracts are missing owing to the absence of the cerebral cortex. Additional anomalies include folding of the ears, cleft palate, and congenital heart defects in 10–20% of cases. Most anencephalic infants die within several days of birth. The incidence of anencephaly approximates 1/1,000 live births, and the greatest frequency is in Ireland and Wales. The recurrence risk is approximately 4% and increases to 10% if a couple has had two previously affected pregnancies. Many factors have been implicated as the cause of anencephaly (in addition to a genetic basis), including low socioeconomic status, nutritional and vitamin deficiencies, and a large number of environmental and toxic factors. It is very likely that several noxious stimuli interact on a genetically susceptible host to produce anencephaly. Fortunately, the frequency of anencephaly has been decreasing during the past 2 decades. Approximately 50% of cases of anencephaly are associated with polyhydramnios. Couples who have had an anencephalic infant should have successive pregnancies monitored, including amniocentesis, determination of AFP levels, and ultrasound examination between the 14th and 16th wk of gestation.

585.7 Disorders of Neuronal Migration

Disorders of neuronal migration may result in minor abnormalities with little or no clinical consequence (e.g., small heterotopia of neurons) or devastating abnormalities of the CNS (e.g., mental retardation, lissencephaly, schizencephaly) (Fig. 585–3). One of the most important mechanisms in the control of neuronal migration is the radial glial fiber system that guides neurons to their proper site. Migrating neurons attach to the radial glial fiber and then disembark at predetermined sites to ultimately form the precisely designed six-layered cerebral cortex. The product of a mouse gene called *reelin* directs the new neuron to reach its final destination in the brain. Another mouse gene (*mdab1*) may act as a signaling pathway triggered by *reelin*. Mutations of these genes in mice produce major neuronal migration abnormalities. The severity and the extent

Figure 585.7-3 T1 weighted MRI scan demonstrating band heterotopia. A thin layer of white matter (*black arrow*) lies between the band of heterotopic gray matter and the cortical surface. Failure of cortical organization with lissencephaly is present in both frontal lobes (*white arrow*).

of the disorder are related to numerous factors, including the timing of a particular insult and a host of environmental and genetic factors.

The embryonic neural tube consists of three zones: ventricular, mantle, and marginal (see Fig. 585–1 *E*). The ependymal layer consists of a pluripotential, pseudostratified, columnar neuroepithelium. Specific neuroepithelial cells differentiate into primitive neurons or neuroblasts that form the mantle layer. The marginal zone is formed from cells in the outer layer of the neuroepithelium, which ultimately becomes the white matter. Glioblasts, which act as the primitive supportive cells of the CNS, also arise from the neuroepithelial cells in the ependymal zone. They migrate to the mantle and marginal zones and become future astrocytes and oligodendrocytes. It is likely that microglia originate from mesenchymal cells at a later stage of fetal development when blood vessels begin to penetrate the developing nervous system. Continued advancement of an understanding of the molecular bases of cortical development is leading to new classifications of malformations of cortical development.

Lissencephaly.

Lissencephaly, or agyria, is a rare disorder that is characterized by the absence of

cerebral convolutions and a poorly formed sylvian fissure, giving the appearance of a 3–4 mo fetal brain. The condition is probably a result of faulty neuroblast migration during early embryonic life and is usually associated with enlarged lateral ventricles and heterotopias in the white matter. There is a four-layered cortex, rather than the usual six-layered one, with a thin rim of periventricular white matter and numerous gray heterotopia visible by microscopic examination. Clinically, these infants present with failure to thrive, microcephaly, marked developmental delay, and a severe seizure disorder. Ocular abnormalities are common, including hypoplasia of the optic nerve and microphthalmia. Lissencephaly can occur as an isolated finding, but it is associated with *Miller-Dieker syndrome* (MDS) in about 15% of cases. These children have characteristic facies, including a prominent forehead, bitemporal hollowing, anteverted nostrils, a prominent upper lip, and micrognathia. About 90% of children with MDS have visible or submicroscopic chromosomal deletions of 17p13.3. The gene *LIS-1* (lissencephaly 1) in 17p13.3 is deleted in patients with MDS. CT and MRI scans typically show a smooth brain with an absence of sulci (Fig. 585–4).

Schizencephaly.

Schizencephaly is the presence of unilateral or bilateral clefts within the cerebral hemispheres due to an abnormality of morphogenesis. The cleft may be fused or unfused and, if unilateral and large, may be confused with a porencephalic cyst. Not infrequently, the borders of the cleft are surrounded by abnormal brain, particularly microgyria. CT scan is diagnostic and clearly demonstrates the size and extent of the cleft. Many patients are severely mentally retarded, with seizures that are difficult to control, and microcephalic, with spastic quadriparesis when the clefts are bilateral.

Porencephaly.

This is the presence of cysts or cavities within the brain that result from developmental defects or acquired lesions, including infarction of tissue. *True porencephalic* cysts are most frequently located in the region of the sylvian fissure and typically communicate with the subarachnoid space, the ventricular system, or both. They represent developmental abnormalities of cell migration and are often associated with other malformations of the brain, including microcephaly, abnormal patterns of adjacent gyri, and encephalocele. Affected infants tend to have many problems, including mental retardation, spastic quadriparesis, optic atrophy, and seizures. *Pseudoporencephalic cysts* characteristically develop during the perinatal or postnatal period and result from abnormalities (infarction, hemorrhage) of arterial or venous circulation. These cysts tend to be unilateral, they do not communicate with a fluid-filled cavity, and

Figure 585.7-4 MRI of an infant with lissencephaly. Note the absence of cerebral sulci and the maldeveloped sylvian fissures associated with enlarged ventricles.

they are not associated with abnormalities of cell migration or CNS malformations. Infants with pseudoporencephalic cysts present with hemiparesis and focal seizures during the 1st year of life.

Holoprosencephaly.

This developmental disorder of the brain results from defective cleavage of the prosencephalon. The abnormality, which represents a spectrum of severity, is classified into three groups: alobar, semilobar, and lobar, depending on the degree of the cleavage abnormality (Fig. 585–5). A fourth type, the middle interhemispheric fusion (MIHF variant) or syntelencephaly, involves a segmental area of noncleavage of the posterior frontal and parietal lobes. Facial abnormalities including cyclopia, cebocephaly, and premaxillary agenesis are common in severe cases, in that the prechordal mesoderm that induces the prosencephalon is also responsible for induction of the median facial structures. The most severe form, alobar holoprosencephaly, is typically associated with neuronal migration disorders. Alobar holoprosencephaly is characterized by a single ventricle, an absent falx, and fused basal ganglia. Affected infants have high mortality rates, but some children live for years. Mortality and morbidity with milder types are more variable and less severe. Care must be taken not to prognosticate in these cases. The incidence of holoprosencephaly ranges from 1/5,000 to 1/16,000. A prenatal diagnosis can be confirmed by ultrasonography after the 10th wk of gestation for more severe types. The cause for holoprosencephaly is usually not identified, although there appears to be an association with maternal diabetes in many cases. Chromosomal abnormalities, including deletions of chromosomes 7q and 3p, 21q, 2p, 18p, and 13q, as well as trisomy 13 and 18, account for the minority of cases. Mutations in the “sonic hedgehog” gene at 7q have been shown to cause holoprosencephaly.

585.8 Agenesis of the Corpus Callosum

Agenesis of the corpus callosum consists of a heterogeneous group of disorders that vary in expression from severe intellectual and neurologic abnormalities to the asymptomatic and normally intelligent individual. The corpus callosum develops from

Figure 585.8-5 Lobar holoprosencephaly. T1 weighted MRI scan demonstrates failure of separation of the hemispheres and a persistent fused ventricle.

the commissural plate that lies in proximity to the anterior neuropore. An insult to the commissural plate during early embryogenesis causes agenesis of the corpus callosum. When agenesis of the corpus callosum is an isolated phenomenon, the patient may be normal, whereas individuals with neurologic symptoms, including mental retardation, microcephaly, hemiparesis, diplegia, and seizures, have associated brain anomalies due to cell migration defects, such as heterotopias, microgyria, and pachygyria (broad, wide gyri) in addition to the absence of the corpus callosum. The anatomic features are best depicted on a CT scan or by MRI and show widely separated frontal horns with an abnormally high position of the third ventricle between the lateral ventricles. MRI precisely outlines the extent of the corpus callosum defect. Absence of the corpus callosum may be inherited as an X-linked recessive trait or as an autosomal dominant trait. The condition may be associated with specific chromosomal disorders, particularly 8-trisomy and 18-trisomy.

Aicardi syndrome represents a complex disorder that affects many systems and is typically associated with agenesis of the corpus callosum. Patients are almost all female, suggesting a genetic abnormality of the X chromosome (it may be lethal in males during fetal life). Seizures become evident during the first few months and are typically resistant to anticonvulsants. An electroencephalogram (EEG) shows independent activity recorded from both hemispheres as a result of the absent corpus callosum. All patients are severely mentally retarded and may have abnormal vertebrae that may be fused or only partially developed (e.g., hemivertebra). Abnormalities of the retina, including circumscribed pits or lacunae and coloboma of the optic disc, are the most characteristic findings of Aicardi syndrome.

585.9 Agenesis of the Cranial Nerves

Absence of the cranial nerves or the corresponding central nuclei has been described in several conditions and includes the optic nerve, congential ptosis, Marcus Gunn phenomenon (sucking jaw movements causing simultaneous eyelid blinking; this congenital synkinesis results from abnormal innervation of the trigeminal and oculomotor nerves), the trigeminal and auditory nerves, and cranial nerves IX, X, XI, and XII. *Möbius syndrome* is characterized by bilateral facial weakness, which is often associated with abducens nerve paralysis. Hypoplasia or agenesis of brainstem nuclei as well as absent or decreased numbers of muscle fibers has been reported. Affected infants present in the newborn period with facial weakness, causing feeding difficulties due to a poor suck. The immobile, dull facies may give the incorrect impression of mental retardation; the prognosis for normal development is excellent in most cases.

585.10 Microcephaly

Microcephaly is defined as a head circumference that measures more than three standard deviations below the mean for age and sex. This condition is relatively common, particularly among the mentally retarded population. Although there are many causes of microcephaly, abnormalities in neuronal migration during fetal development, including heterotopias of neuronal cells and cytoarchitectural derangements, are found in many brains. Microcephaly may be subdivided into two main groups: primary (genetic) microcephaly and secondary (nongenetic) microcephaly. A precise diagnosis is important for genetic counseling and for prediction for future pregnancies.

Etiology.

Primary microcephaly refers to a group of conditions that usually have no other malformations and follow a mendelian pattern of inheritance or are associated with a specific genetic syndrome. Affected infants are usually identified at birth because of a small head circumference. The more common types include familial and autosomal dominant microcephaly and a series of chromosomal syndromes that are summarized in Table 585–1 . Secondary microcephaly results from a large number of noxious agents that may affect a fetus in utero or an infant during periods of rapid brain growth, particularly the first 2 yr of life.

Clinical Manifestations and Diagnosis.

A thorough family history should be taken, seeking additional cases of microcephaly or disorders affecting the nervous system. It is important to measure a patient's head circumference at birth. A very small head circumference implies a process that began early in embryonic or fetal development. An insult to the brain that occurs later in life, particularly beyond the age of 2 yr, is less likely to produce severe microcephaly. Serial head circumference measurements are more meaningful than a single determination, particularly when the abnormality is minimal. In addition, the head circumference of each parent and sibling should be recorded.

Laboratory investigation of a microcephalic child is determined by the history and physical examination. If the cause of the microcephaly is unknown, the mother's serum phenylalanine level should be determined. High phenylalanine serum levels in an asymptomatic mother can produce marked brain damage in an otherwise normal nonphenylketonuric infant. A karyotype is obtained if a chromosomal syndrome is suspected or if the child has abnormal facies, short stature, and additional congenital anomalies. CT scanning or MRI may be useful in identifying structural abnormalities of the brain or intracerebral calcification. Additional studies include a fasting plasma

and urine amino acid analysis; serum ammonium determination; *t*oxoplasmosis, *r*ubella, *c*ytomegalovirus, and *h*erpes simplex (TORCH) titers of the mother and child; and a urine sample for the culture of cytomegalovirus.

Treatment.

Once the cause of microcephaly has been established, the physician must provide accurate and supportive genetic and family counseling. Because many children with microcephaly are also mentally retarded, the physician must assist with placement

TABLE 585.10-1 -- **Causes of Microcephaly**

Causes	Characteristic Findings
Primary (Genetic)	
1. Familial (autosomal recessive)	• Incidence 1/40,000 births • Typical appearance with slanted forehead, prominent nose and ears; severely mentally retarded and prominent seizures; surface convolutional markings of the brain poorly differentiated and disorganized cytoarchitecture
2. Autosomal dominant	• Nondistinctive facies, up-slanting palpebral fissures, mild forehead slanting, and prominent ears • Normal linear growth, seizures readily controlled, and mild or borderline mental retardation
3. Syndromes	
Down (21-trisomy)	• Incidence 1/800 • Abnormal rounding of occipital and frontal lobes and a small cerebellum; narrow superior temporal gyrus, propensity for Alzheimer's neurofibrillary alterations, and ultrastructure abnormalities of cerebral cortex
Edward (18-trisomy)	• Incidence 1/6,500 • Low birthweight, microstomia, micrognathia, low-set malformed ears, prominent occiput, rocker-bottom feet, flexion deformities of fingers, congenital heart disease, increased gyri, heterotopias of neurons
Cri-du-chat (5 p-)	• Incidence 1/50,000 • Round facies, prominent epicanthic folds, low-set ears, hypertelorism, and characteristic cry • No specific neuropathology
Cornelia de Lange	• Prenatal and postnatal growth delay, synophrys, thin down-turning upper lip • Proximally placed thumb
Rubinstein-Taybi	• Beaked nose, downward slanting of palpebral fissures, epicanthic folds, short stature with broad thumbs and toes
Smith-Lemli-Opitz	• Ptosis, scaphocephaly, inner epicanthic folds, anteverted nostrils • Low birthweight, marked feeding problems
Secondary (Nongenetic)	
1. Radiation	• Microcephaly and mental retardation most severe if exposure before 15th wk of gestation
2. Congenital infections	
Cytomegalovirus	• Small for dates, petechial rash, hepatosplenomegaly, chorioretinitis, deafness, mental retardation, and seizures • Central nervous system calcification and microgyria
Rubella	• Growth retardation, purpura, thrombocytopenia, hepatosplenomegaly, congenital heart disease, chorioretinitis, cataracts, and deafness • Perivascular necrotic areas, polymicrogyria, heterotopias, subependymal cavitations
Toxoplasmosis	• Purpura, hepatosplenomegaly, jaundice, convulsions, hydrocephalus, chorioretinitis, and cerebral calcification
3. Drugs	
Fetal alcohol	• Growth retardation, ptosis, absent philtrum and hypoplastic upper lip, congenital heart disease, feeding problems, neuroglial heterotopia, and disorganization of neurons
Fetal hydantoin	• Growth delay, hypoplasia of distal phalanges, inner epicanthic folds, broad nasal ridge, and anteverted nostrils
4. Meningitis/encephalitis	• Cerebral infarcts, cystic cavitation, diffuse loss of neurons
5. Malnutrition	• Controversial cause of microcephaly
6. Metabolic	• Maternal diabetes mellitus and maternal hyperphenylalaninemia
7. Hyperthermia	• Significant fever during 1st 4–6 wk has been reported to cause microcephaly, seizures, and facial anomalies • Pathologic studies show neuronal heterotopias • Further studies showed no abnormalities with maternal fever
8. Hypoxic-ischemic encephalopathy	• Initially diffuse cerebral edema; late stages characterized by cerebral atrophy

in an appropriate program that will provide for maximum development of the child (see Chapter 37.2). **REFERENCES**

585.11 Hydrocephalus

Hydrocephalus is not a specific disease; rather, it represents a diverse group of conditions that result from impaired circulation and absorption of CSF or, in the rare circumstance, from increased production by a choroid plexus papilloma.

Physiology.

The CSF is formed primarily in the ventricular system by the choroid plexus, which is situated in the lateral, third, and fourth ventricles. Although most CSF is produced in the lateral ventricles, approximately 25% originates from extrachoroidal sources, including the capillary endothelium within the brain parenchyma. There is active neurogenic control of CSF formation as the choroid plexus is innervated by adrenergic and cholinergic nerves. Stimulation of the adrenergic system diminishes CSF production, whereas excitation of the cholinergic nerves may double the normal CSF production rate. In a normal child, approximately 20?mL/hr of CSF is produced. The total volume of CSF approximates 50?mL in an infant and 150?mL in an adult. Most of the CSF is extraventricular. CSF is formed by the choroid plexus in several stages; through a series of intricate steps, a plasma ultrafiltrate is ultimately processed into a secretion, the CSF.

CSF flow results from the pressure gradient that exists between the ventricular system and venous channels. Intraventricular pressure may be as high as 180?mm H_2O in the normal state, whereas the pressure in the superior sagittal sinus is in the range of 90?mm H_2O. Normally, CSF flows from the lateral ventricles through the foramina of Monro into the third

ventricle. It then traverses the narrow aqueduct of Sylvius, which is approximately 3?mm long and 2?mm in diameter in a child, to enter the fourth ventricle. The CSF exits the fourth ventricle through the paired lateral foramina of Luschka and the midline foramen of Magendie into the cisterns at the base of the brain. Hydrocephalus resulting from obstruction within the ventricular system is called *obstructive* or *noncommunicating hydrocephalus*. The CSF circulates from the basal cisterns posteriorly through the cistern system and over the convexities of the cerebral hemispheres. CSF is absorbed primarily by the arachnoid villi through tight junctions of their endothelium by the pressure forces that were noted earlier. CSF is absorbed to a much lesser extent by the lymphatic channels directed to the paranasal sinuses, along nerve root sleeves, and by the choroid plexus itself.

Hydrocephalus resulting from obliteration of the subarachnoid cisterns or malfunction of the arachnoid villi is called *nonobstructive* or *communicating hydrocephalus*.

Pathophysiology and Etiology.

Obstructive or noncommunicating hydrocephalus develops most commonly in children because of an abnormality of the aqueduct or a lesion in the fourth ventricle. *Aqueductal stenosis* results from an abnormally narrow aqueduct of Sylvius that is often associated with branching or forking. In a small percentage of cases, aqueductal stenosis is inherited as a sex-linked recessive trait. These patients occasionally have minor neural tube closure defects, including spina bifida occulta. Rarely, aqueductal stenosis is associated with neurofibromatosis. *Aqueductal gliosis* may also give rise to hydrocephalus. As a result of neonatal meningitis or a subarachnoid hemorrhage in a premature infant, the ependymal lining of the aqueduct is interrupted and a brisk glial response results in complete obstruction. Intrauterine viral infections may also produce aqueductal stenosis followed by hydrocephalus, and mumps meningoencephalitis has been reported as a cause in a child. A vein of Galen malformation can expand to become large and, because of its midline position, obstruct the flow of CSF. Lesions or malformations of the posterior fossa are prominent causes of hydrocephalus, including posterior fossa brain tumors, Chiari malformation, and the Dandy-Walker syndrome.

Nonobstructive or communicating hydrocephalus most commonly follows a subarachnoid hemorrhage, which is usually a result of intraventricular hemorrhage in a premature infant. Blood in the subarachnoid spaces may cause obliteration of the cisterns or arachnoid villi and obstruction of CSF flow. Pneumococcal and tuberculous meningitis have a propensity to produce a thick, tenacious exudate that obstructs the basal cisterns, and intrauterine infections may also destroy the CSF pathways. Finally, leukemic infiltrates may seed the subarachnoid space and produce communicating hydrocephalus.

Clinical Manifestations.

The clinical presentation of hydrocephalus is variable and depends on many factors, including the age at onset, the nature of the lesion causing obstruction, and the duration and rate of increase of the intracranial pressure (ICP). In an infant, an accelerated rate of enlargement of the head is the most prominent sign. In addition, the anterior fontanel is wide open and bulging, and the scalp veins are dilated. The forehead is broad, and the eyes may deviate downward because of impingement of the dilated suprapineal recess on the tectum, producing the setting-sun eye sign. Long-tract signs including brisk tendon reflexes, spasticity, clonus (particularly in the lower extremities), and Babinski sign are common owing to stretching and disruption of the corticospinal fibers originating from the leg region of the motor cortex. In an older child, the cranial sutures are partially closed so that the signs of hydrocephalus may be more subtle. Irritability, lethargy, poor appetite, and vomiting are common to both age groups, and headache is a prominent symptom in older patients. A gradual change in personality and deterioration in academic productivity suggest a slowly progressive form of hydrocephalus. Serial measurements of the head circumference indicate an increased velocity of growth. Percussion of the skull may produce a "cracked-pot" or **Macewen Sign,** indicating separation of the sutures. A foreshortened occiput suggests Chiari malformation, and a prominent occiput suggests the Dandy-Walker malformation. Papilledema, abducens nerve palsy, and pyramidal tract signs, which are most evident in the lower extremities, are apparent in most cases.

Chiari malformation consists of two major subgroups; type I typically produces symptoms during adolescence or adult life and is usually not associated with hydrocephalus. Patients complain of recurrent headache, neck pain, urinary frequency, and progressive lower extremity spasticity. The deformity consists of displacement of the cerebellar tonsils into the cervical canal. Although the pathogenesis is unknown, the prevailing theory suggests that obstruction of the caudal portion of the fourth ventricle during fetal development is responsible. The type II Chiari malformation is characterized by progressive hydrocephalus and a myelomeningocele. This lesion represents an anomaly of the hindbrain, probably due to a failure of pontine flexure during embryogenesis, and results in elongation of the fourth ventricle and kinking of the brainstem, with displacement of the inferior vermis, pons, and medulla into the cervical canal (Fig. 585–6). Approximately 10% of type II malformations produce symptoms during infancy consisting of stridor, weak cry, and apnea, which may be relieved by shunting or by posterior fossa decompression. A more indolent form consists of abnormalities of gait, spasticity, and increasing incoordination during childhood. Plain skull radiographs show a small posterior fossa and a widened cervical canal. CT scanning with contrast and MRI display the cerebellar tonsils protruding downward into the cervical canal and the hindbrain abnormalities. The anomaly is treated by surgical decompression.

The *Dandy-Walker malformation* consists of a cystic expansion of the fourth ventricle in the posterior fossa, which results from a developmental failure of the roof of the 4th ventricle during embryogenesis (Fig. 585–7). Approximately 90% of patients

Figure 585.11-6 A midsagittal T1 weighted MRI of a patient with type II Chiari malformation. The cerebellar tonsils (*white arrow*) have descended below the foramen magnum (*black arrow*). Note the small slitlike 4th ventricle, which has been pulled into a vertical position.

Figure 585.11-7 Dandy-Walker cyst. *A,* Axial CT scan (preoperative) showing large posterior fossa cyst (Dandy-Walker cyst; *large arrows*) and dilated lateral ventricles (*small arrows*), a complication secondary to CSF pathway obstruction at the 4th ventricular outlet. *B,* Same patient, with a lower axial CT scan showing splaying of the cerebellar hemispheres by the dilated 4th ventricle (Dandy-Walker cyst). The dilated ventricles proximal to the 4th ventricle again show CSF obstruction due to the Dandy-Walker cyst. *C,* MRI of the same patient showing decreased size of the Dandy-Walker cyst and temporal horns (*arrows*) following shunting. The incomplete vermis (*small arrow*) now becomes recognizable.

have hydrocephalus, and a significant number of children have associated anomalies, including agenesis of the posterior cerebellar vermis and corpus callosum. Infants present with a rapid increase in head size and a prominent occiput. Transillumination of the skull may be positive. Most children have evidence of long-tract signs, cerebellar ataxia, and delayed motor and cognitive milestones, probably due to the associated structural anomalies. The Dandy-Walker malformation is managed by shunting the cystic cavity (and on occasion the ventricles as well) in the presence of hydrocephalus.

Diagnosis and Differential Diagnosis.

Investigation of a child with hydrocephalus begins with the history. Familial cases suggest X-linked hydrocephalus secondary to aqueductal stenosis. A past history of prematurity with intracranial hemorrhage, meningitis, or mumps encephalitis is important to ascertain. Multiple café-au-lait spots and other clinical features of neurofibromatosis point to aqueductal stenosis as the cause of hydrocephalus. Examination includes careful inspection, palpation, and auscultation of the skull and spine. The occipitofrontal head circumference is recorded and compared with previous measurements. The size and configuration of the anterior fontanel are noted, and the back is inspected for abnormal midline skin lesions, including tufts of hair, lipoma, or angioma that might suggest spinal dysraphism. The presence of a prominent forehead or abnormalities in the shape of the occiput may suggest the pathogenesis of the hydrocephalus. A cranial bruit is audible in association with many cases of vein of Galen arteriovenous malformation. Transillumination of the skull is positive with massive dilatation of the ventricular system or in the Dandy-Walker syndrome. Inspection of the eyegrounds is mandatory because the finding of chorioretinitis suggests an intrauterine infection such as toxoplasmosis as a cause of the hydrocephalus. Papilledema is observed in older children but is rarely present in infants because the cranial sutures separate as a result of the increased pressure. Plain skull films typically show separation of the sutures, erosion of the posterior clinoids in an older child, and an increase in convolutional markings (beaten-silver appearance) with long-standing increased ICP. The CT scan and/or MRI along with ultrasonography in an infant are the most important studies to identify the specific cause of hydrocephalus.

The head may appear enlarged and be confused with hydrocephalus secondary to a thickened cranium resulting from chronic anemia, rickets, osteogenesis imperfecta, and epiphyseal dysplasia. Chronic subdural collections can produce bilateral parietal bone prominence. Various metabolic and degenerative disorders of the CNS produce megalencephaly due to abnormal storage of substances within the brain parenchyma. These disorders include lysosomal diseases (e.g., Tay-Sachs, gangliosidosis, and the mucopolysaccharidoses), the aminoacidurias (e.g., maple syrup urine disease), and the leukodystrophies (e.g., metachromatic, Alexander disease, and Canavan disease). In addition, cerebral gigantism and neurofibromatosis are characterized by increased brain mass. Familial megalencephaly is inherited as an autosomal dominant trait and is characterized by delayed motor milestones and hypotonia but normal or near-normal intelligence. Measurement of the parent's head circumference is necessary to establish the diagnosis.

Hydranencephaly may be confused with hydrocephalus. The cerebral hemispheres are absent or represented by membranous sacs with remnants of frontal, temporal, or occipital cortex dispersed over the membrane. The midbrain and brainstem are relatively intact (Fig. 585–8). The cause of hydranencephaly is unknown, but bilateral occlusion of the internal carotid arteries during early fetal development would explain most of the pathologic abnormalities. Affected infants may have a normal or enlarged head circumference at birth that grows at an excessive rate postnatally. Transillumination shows an absence of the cerebral hemispheres. The child is irritable, feeds poorly, develops seizures and spastic quadriparesis, and has little or no cognitive development. A ventriculoperitoneal shunt prevents massive enlargement of the cranium.

Treatment.

Therapy for hydrocephalus depends on the cause. Medical management, including the use of acetazolamide and furosemide, may provide temporary relief by reducing the rate of CSF production, but long-term results have been disappointing. Most cases of hydrocephalus require extracranial shunts, particularly a ventriculoperitoneal shunt (occasionally a ventriculostomy suffices). The major complication of shunts is bacterial infection, usually due to *Staphylococcus epidermidis* (see Chapter 166). With meticulous preparation, the shunt infection rate can be reduced to less than 5%. The results of intrauterine surgical management of fetal hydrocephalus have been poor, possibly because of the high rate of associated cerebral malformations in addition to the hydrocephalus.

Figure 585.11-8 Hydranencephaly. MRI scan showing the brainstem and spinal cord with remnants of the cerebellum and the cerebral cortex. The remainder of the cranium is filled with CSF.

Prognosis.

This depends on the cause of the dilated ventricles and not on the size of the cortical mantle at the time of operative intervention. Hydrocephalic children are at increased risk for various developmental disabilities. The mean intelligence quotient is reduced compared with the general population, particularly for performance tasks as compared with verbal abilities. Most children have abnormalities in memory function. Visual problems are common, including strabismus, visuospatial abnormalities, visual field defects, and optic atrophy with decreased acuity secondary to increased ICP. The visual-evoked potential latencies are delayed and take some time to recover after correction of the hydrocephalus. Although most hydrocephalic children are pleasant and mild mannered, some children show aggressive and delinquent behavior. Accelerated pubertal development in patients with shunted hydrocephalus or meningomyelocele is relatively common, possibly because of increased gonadotropin secretion in response to increased ICP. It is imperative that hydrocephalic children receive long-term follow-up in a multidisciplinary setting.

585.12 Craniosynostosis

Craniosynostosis is defined as premature closure of the cranial sutures and is classified as primary or secondary. *Primary craniosynostosis* refers to closure of one or more sutures due to abnormalities of skull development, whereas *secondary craniosynostosis* results from failure of brain growth and expansion and is not discussed here. The incidence of primary craniosynostosis approximates 1/2,000 births. The cause is unknown in the majority of children; however, genetic syndromes account for 10–20% of cases.

Development and Etiology.

A review of skull development is helpful in understanding the genesis of craniosynostosis. During early development, the brain is enveloped by a film of mesenchyme. By the 2nd mo, osseous tissue is evident in that portion of the mesenchyme corresponding to the cranium, and cartilaginous tissue is formed at the base of the skull. The bones of the cranium are well developed by the 5th mo of gestation (frontal, parietal, temporal, and occipital) and are separated by sutures and fontanels. The brain grows rapidly during the first several years of life and is normally not impeded because of equivalent growth along the suture lines. The cause of craniosynostosis is unknown, but the prevailing hypothesis suggests that abnormal development of the base of the skull creates exaggerated forces on the dura that act to disrupt normal cranial suture development. Dysfunctional osteoblasts or osteoclasts are not responsible for craniosynostosis.

Clinical Manifestations and Treatment.

Most cases of craniosynostosis are evident at birth and are characterized by a skull deformity that is a direct result of premature suture fusion. Palpation of the suture reveals a prominent bony ridge, and fusion of the suture may be confirmed by plain skull roentgenograms or bone scan in ambiguous cases.

Premature closure of the sagittal suture produces a long and narrow skull, or *scaphocephaly*, the most common form of craniosynostosis. Scaphocephaly is associated with a prominent occiput, a broad forehead, and a small or absent anterior fontanel. The condition is sporadic and more common in males and often causes difficulties during labor because of cephalopelvic disproportion. Scaphocephaly does not produce increased ICP or hydrocephalus, and results of neurologic examination of affected patients are normal.

Frontal plagiocephaly is the next most common form of craniosynostosis and is characterized by unilateral flattening of the forehead, elevation of the ipsilateral orbit

and eyebrow, and a prominent ear on the corresponding side. The condition is more common in females and is the result of premature fusion of a coronal and sphenofrontal suture. Surgical intervention produces a cosmetically pleasing result.

Occipital plagiocephaly is most often a result of positioning during infancy and is more common in an immobile or handicapped child, but fusion or sclerosis of the lambdoid suture can cause unilateral occipital flattening and bulging of the ipsilateral frontal bone. *Trigonocephaly* is a rare form of craniosynostosis due to premature fusion of the metopic suture. These children have a keel-shaped forehead and hypotelorism and are at risk for associated developmental abnormalities of the forebrain. *Turricephaly* refers to a cone-shaped head due to premature fusion of the coronal and often sphenofrontal and frontoethmoidal sutures. The *kleeblattschädel deformity* is a peculiarly shaped skull that resembles a cloverleaf. Affected children have very prominent temporal bones, and the remainder of the cranium is constricted. Hydrocephalus is a common complication.

Premature fusion of only one suture rarely causes a neurologic deficit. In this situation, the sole indication for surgery is to enhance the child's cosmetic appearance, and the prognosis depends on the suture involved and on the degree of disfigurement. Neurologic complications, including hydrocephalus and increased ICP, are more likely to occur when two or more sutures are prematurely fused, in which case operative intervention is essential.

The most prevalent genetic disorders associated with craniosynostosis include Crouzon, Apert, Carpenter, Chotzen, and Pfeiffer syndromes. *Crouzon syndrome* is characterized by premature craniosynostosis and is inherited as an autosomal dominant trait. The shape of the head depends on the timing and order of suture fusion but most often is a compressed back-to-front diameter or brachycephaly due to bilateral closure of the coronal sutures. The orbits are underdeveloped, and ocular proptosis is prominent. Hypoplasia of the maxilla and orbital hypertelorism are typical facial features.

Apert syndrome has many features in common with Crouzon syndrome. However, Apert syndrome is usually a sporadic condition, although autosomal dominant inheritance may occur. It is associated with premature fusion of multiple sutures, including the coronal, sagittal, squamosal, and lambdoid sutures. The facies tend to be asymmetric, and the eyes are less proptotic than in Crouzon syndrome. Apert syndrome is characterized by syndactyly of the 2nd, 3rd, and 4th fingers, which may be joined to the thumb and the 5th finger. Similar abnormalities often occur in the feet. All patients have progressive calcification and fusion of the bones of the hands, feet, and cervical spine.

Carpenter syndrome is inherited as an autosomal recessive condition, and the many fusions of sutures tend to produce the kleeblattschädel skull deformity. Soft-tissue syndactyly of the hands and feet is always present, and mental retardation is common.

Additional but less common abnormalities include congenital heart disease, corneal opacities, coxa valga, and genu valgum.

Chotzen syndrome is characterized by asymmetric craniosynostosis and plagiocephaly. The condition is the most prevalent of the genetic syndromes and is inherited as an autosomal dominant trait. It is associated with facial asymmetry, ptosis of the eyelids, shortened fingers, and soft tissue syndactyly of the 2nd and 3rd fingers.

Pfeiffer syndrome is most often associated with turricephaly. The eyes are prominent and widely spaced, and the thumbs and great toes are short and broad. Partial soft tissue syndactyly may be evident. Most cases appear to be sporadic, but autosomal dominant inheritance has been reported.

Mutations of the fibroblast growth factor receptor (FGFR) gene family have been shown to be associated with phenotypically specific types of craniosynostosis. Mutations of the $FGFR_1$ gene located on chromosome 8 result in Pfeiffer syndrome; a similar mutation of the $FGFR_2$ gene causes Apert syndrome. Identical mutations of the $FGFR_2$ gene may result in both Pfeiffer and Crouzon phenotypes.

Each of the genetic syndromes poses a risk of additional anomalies, including hydrocephalus, increased ICP, papilledema, optic atrophy due to abnormalities of the optic foramina, respiratory problems secondary to a deviated nasal septum or choanal atresia, and disorders of speech and deafness. Craniectomy is mandatory for management of increased ICP, and a multidisciplinary craniofacial team is essential for the long-term follow-up of affected children. Craniosynostosis may be surgically corrected with good outcomes and relatively low morbidity and mortality, especially for nonsyndromic infants.

Chapter 586 - Seizures in Childhood

Michael V. Johnston

A seizure or convulsion is a paroxysmal, time-limited change in motor activity and/or behavior that results from abnormal electrical activity in the brain. Seizures are common in the pediatric age group and occur in approximately 10% of children. Most seizures in children are provoked by somatic disorders originating outside the brain, such as high fever, infection, syncope, head trauma, hypoxia, toxins, or cardiac arrhythmias. Other events, such as breath-holding spells and gastroesophageal reflux, can cause events that simulate seizures (see Chapter 587). A few children also exhibit psychogenic seizures of psychiatric origin. Less than one third of seizures in children are caused by epilepsy, a condition in which seizures are triggered recurrently from within the brain. For epidemiologic classification purposes, epilepsy is considered to be present when two or more unprovoked seizures occur at an interval greater than 24?hr apart. The cumulative lifetime incidence of epilepsy is 3% and more than half of cases begin in childhood. However, the annual prevalence of epilepsy is lower (0.5–0.8%) because many children outgrow epilepsy. Although the outlook for most children with symptomatic seizures or those associated with epilepsy is generally good, the seizures may signal a potentially serious underlying systemic or central nervous system (CNS) disorder that requires thorough investigation and management. For children with epilepsy, the prognosis is generally good, but 10–20% have persistent seizures refractory to drugs, and those cases pose a diagnostic and management challenge.

Evaluation of the First Seizure.

Initial evaluation of an infant or child during or shortly after a suspected seizure should include an assessment of the adequacy of the airway, ventilation, and cardiac function as well as measurement of temperature, blood pressure, and glucose concentration. For acute evaluation of the first seizure, the physician should search for potentially life-threatening causes of seizures such as meningitis, systemic sepsis, accidental and nonaccidental head trauma, and ingestion of drugs of abuse and other toxins. The *history* should attempt to define factors that may have promoted the convulsion and to provide a detailed description of the seizure and the child's postictal state. Most parents vividly recall their child's initial convulsion and can describe it in detail.

The first step in an evaluation is to determine whether the seizure has a focal onset or is generalized. *Focal seizures* may be characterized by motor or sensory symptoms and include forceful turning of the head and eyes to one side, unilateral clonic movements beginning in the face or extremities, or a sensory disturbance such as paresthesias or pain localized to a specific area. Focal seizures in an adult usually indicate a localized lesion, but investigation of focal seizures during childhood may be nondiagnostic. Motor seizures may be focal or generalized and tonic-clonic, tonic, clonic, myoclonic, or atonic. *Tonic seizures* are characterized by increased tone or rigidity, and *atonic seizures* are characterized by flaccidity or lack of movement during a convulsion. *Clonic seizures* consist of rhythmic muscle contraction and relaxation, and *myoclonus* is most accurately described as shocklike contraction of a muscle. The duration of the seizure and state of consciousness (retained or impaired) should be documented. The history should determine whether an aura preceded the convulsion and the behavior of the child immediately preceding the seizure. The most common aura experienced by children consists of epigastric discomfort or pain and a feeling of fear. The posture of the patient, presence and distribution of cyanosis, vocalizations, loss of sphincter control (particularly of the urinary bladder), and postictal state (including sleep and headache) should be noted.

In addition to the assessment of cardiorespiratory and metabolic status described above, *examination* of a child with a seizure disorder should be geared toward the search for an organic cause. The child's head circumference, length, and weight are plotted on a growth chart and compared with previous measurements. A careful general and neurologic examination should be performed. The eyegrounds must be examined for the presence of papilledema, retinal hemorrhages, chorioretinitis, coloboma, and macular changes, as well as retinal phakoma. The finding of unusual facial features or associated physical findings such as hepatosplenomegaly point to an underlying metabolic or storage disease as the cause of the neurologic disorder. A search for vitiliginous lesions of tuberous sclerosis using an ultraviolet light source, examination for adenoma sebaceum, shagreen patch, multiple café-au-lait spots, or a nevus flammeus, and the presence of retinal phakoma would indicate a neurocutaneous disorder as the cause of the seizure.

Localizing neurologic signs such as a subtle hemiparesis with hyperreflexia, an equivocal Babinski sign, and a downward-drifting extended arm with eyes closed might suggest a contralateral hemispheric structural lesion, such as a slow-growing temporal lobe glioma, as the cause of the seizure disorder. Unilateral growth arrest of the thumbnail, hand, or extremity in a child with a focal seizure disorder suggests a chronic condition such as a porencephalic cyst, arteriovenous malformation, or cortical atrophy in the opposite hemisphere.

586.1 Febrile Seizures

Febrile convulsions, the most common seizure disorder during childhood, generally have an excellent prognosis but may also signify a serious underlying acute infectious disease such as sepsis or bacterial meningitis. Therefore, each child with a seizure associated with fever must be carefully examined and appropriately investigated for the cause of the fever (see Chapter 162), especially when it is the first seizure. Febrile seizures are age dependent and are rare before 9 mo and after 5 yr of age. The peak age of onset is approximately 14–18 mo of age, and the incidence approaches 3–4% of young children. A strong family history of febrile convulsions in siblings and parents suggests a genetic predisposition. Linkage studies in several large families have mapped the febrile seizure gene to chromosomes 19p and 8q13-21. An autosomal dominant inheritance pattern is demonstrated in some families.

Clinical Manifestations.

A simple febrile convulsion is usually associated with a core temperature that increases rapidly to 39℃ or greater. The seizure is usually generalized, is tonic-clonic and lasts a few seconds to 10-min, and is followed by a brief postictal period of drowsiness. A febrile seizure is described as atypical or complicated when the duration is longer than 15?min, when repeated convulsions occur within the same day, or when focal seizure activity or focal findings are present during the postictal period.

Approximately 30–50% of children have recurrent seizures with later episodes of fever and a small minority have numerous recurrent seizures. Although children with simple febrile seizures are at no greater risk of later epilepsy than the general population, some factors are associated with increased risk. These include the presence of atypical features of the seizure or postictal period, a positive family history of epilepsy, an initial febrile seizure before 9 mo of age, delayed developmental milestones, or a pre-existing neurologic disorder. The incidence of epilepsy is approximately 9% when several risk factors are present, compared with an incidence of 1% in children who have febrile convulsions and no risk factors.

During the acute evaluation, a physician's most important responsibility is to determine the cause of the fever and to rule out meningitis. *If any doubt exists about the possibility of meningitis, a lumbar puncture with examination of the cerebrospinal fluid (CSF) is indicated*. Seizure-induced CSF abnormalities are rare in children and all patients with abnormal CSF after a seizure should be thoroughly evaluated for other causes. The possibility of viral meningoencephalitis should also be kept in mind, especially that caused by herpes simplex. Viral infections of the upper respiratory tract, roseola, and acute otitis media are most frequently the causes of

febrile convulsions.

Aside from glucose determination, laboratory testing such as serum electrolytes and toxicology screening should be ordered based on individual clinical circumstances such as evidence of dehydration. An electroencephalogram (EEG) is not warranted after a simple febrile seizure but may be useful for evaluating patients with an atypical feature or with other risk factors for later epilepsy. Similarly, neuroimaging is also not useful for children with simple febrile convulsions, but may be considered for children with atypical features, including focal neurologic signs or pre-existing neurologic deficits.

Treatment.

Routine treatment of a normal infant with simple febrile convulsions includes a careful search for the cause of the fever, active measures to control the fever, including the use of antipyretics, and reassurance of the parents. Prolonged anticonvulsant prophylaxis for preventing recurrent febrile convulsions is controversial and no longer recommended. Antiepileptics such as phenytoin and carbamazepine have no effect on febrile seizures. Phenobarbital can be effective in preventing recurrent febrile seizures but may also decrease cognitive function in treated children compared with untreated children. Sodium valproate is also effective in the management of febrile seizures, but the potential risks of the drug do not justify its use in a disorder with an excellent prognosis regardless of treatment. The incidence of fatal valproate-induced hepatotoxicity is highest in children younger than 2 yr of age. Oral diazepam is an effective and safe method of reducing the risk of recurrence of febrile seizures. At the onset of each febrile illness, oral diazepam, 0.3?mg/kg q8h (1?mg/kg/24?hr), is administered for the duration of the illness (usually 2–3 days). The side effects are usually minor, but symptoms of lethargy, irritability, and ataxia may be reduced by adjusting the dose. This strategy may be useful when parental anxiety associated with febrile seizures is severe.

586.2 Unprovoked Seizures

First Seizure.

Although the occurrence of a seizure in a child without a provocative stimulus such as high fever is often considered a harbinger of a chronic seizure disorder or epilepsy, less than half of these children go on to develop a second seizure. A careful history is warranted to ascertain a potential family history of epilepsy, a prior neurologic disorder, or history of seizure with fever, which may increase the likelihood of recurrence. As for febrile seizures, laboratory testing of serum electrolytes, toxicology screening, or urine and serum metabolic testing should be chosen based on individual clinical circumstances rather than on a routine basis. In the child with a first nonfebrile seizure, a lumbar puncture is of limited value and should be used primarily when there is concern about possible meningitis, encephalitis, sepsis, subarachnoid hemorrhage, or a demyelinating disorder. An EEG, however, is recommended as part of the neurodiagnostic evaluation of the child with an apparent first unprovoked seizure because it is useful for diagnosis of the event, prediction of recurrence risk, and identification of specific focal abnormalities and/or epileptic syndromes. Neuroimaging is generally not recommended after a first unprovoked seizure unless there is an indication for it on neurologic examination. If it is obtained, however, MRI of the brain is recommended over CT scanning. Anticonvulsant medication is generally not recommended after a single seizure.

Recurrent Seizures.

Two unprovoked seizures greater than 24 hours apart suggest the presence of an epileptic disorder within the brain that will lead to future recurrences. It is important to perform a careful evaluation to look for the cause of the seizures as well as to assess the need for treatment with antiepileptic drugs and estimate the potential for response to treatment and remission of seizures in the future.

The *history* can provide important information about the type of seizures. Some parents can precisely act out or re-create a seizure. Children who have a propensity to develop epilepsy may experience the first convulsion in association with a viral illness or a low-grade fever. Seizures that occur during the early morning hours or with drowsiness, particularly during the initial phase of sleep, are common in childhood epilepsy. In retrospect, irritability, mood swings, headache, and subtle personality changes may precede a seizure by several days. Some parents can accurately predict the timing of the next seizure on the basis of changes in the child's disposition. The physical portrayal of the convulsion by the parent or caregiver is often surprisingly similar to the actual convulsion and is much more accurate than

the verbal description. Aside from the description of the seizure pattern, the frequency, time of day, precipitating factors, and alternation in the type of convulsive disorder are important. Although generalized tonic-clonic seizures are readily documented, the frequency of absence seizures is often underestimated by parents. A prolonged personality change or intellectual deterioration may suggest a degenerative disease of the CNS, whereas constitutional symptoms, including vomiting

and failure to thrive, might indicate a primary metabolic disorder or a structural lesion. It is essential to obtain details of prior anticonvulsant medication and the child's response to the regimen and to determine whether drugs that may potentiate seizures, including chlorpromazine or methylphenidate, were prescribed. The description of the seizure along with the family history can provide clues to the presence of possible genetic epileptic syndromes. These include autosomal dominant nocturnal frontal lobe epilepsy, familial benign neonatal convulsions, familial benign infantile convulsions, autosomal dominant febrile seizures, partial epilepsy with auditory symptoms, autosomal dominant frontal lobe progressive epilepsy with mental retardation, absence epilepsy, and febrile seizures with later partial complex seizures.

The physical, ophthalmologic, and neurologic *examination* can provide information about the presence of increased intracranial pressure, neurocutaneous syndromes, and structural brain abnormalities including malformations, injuries, infections, or tumors.

The EEG is useful for determining the type of epilepsy and the future prognosis. Measurement of serum electrolytes including calcium and magnesium is not recommended as a routine practice. Metabolic testing, including administration of pyridoxine for suspected pyridoxine-responsive seizures, serum lactate and pyruvate, and urine organic acids, is also not recommended routinely but should be dictated by clinical circumstances. Lumbar puncture should be considered for children with repeated seizures and other evidence of neurodevelopmental disability. It may be useful for detecting low CSF glucose in the glucose transporter disorder, alterations in amino acids, neurotransmitters, or cofactors in metabolic disorders, or evidence of chronic infection. Neuroimaging with MRI should be considered during the evaluation of children with newly diagnosed epilepsy, especially for those with neurologic deficits or partial seizures or focal EEG abnormalities that are not part of an idiopathic localization-related epilepsy syndrome.

Classification of Seizures.

It is important to classify the type of seizure for several reasons. First, the seizure type may provide a clue to the cause of the seizure disorder. In addition, precise delineation of the seizure may allow a firm basis for making a prognosis and choosing the most appropriate treatment. Anticonvulsants may readily control generalized tonic-clonic epilepsy in a child, but a patient with multiple seizure types or partial seizures may fare less well with the same type of therapy.

Box 586.2-1. International Classification of Epileptic Seizures

PARTIAL SEIZURES

- Simple partial (consciousness retained)
  - Motor
  - Sensory
  - Autonomic
  - Psychic
- Complex partial (consciousness impaired)
  - Simple partial, followed by impaired consciousness
  - Consciousness impaired at onset
- Partial seizures with secondary generalization

GENERALIZED SEIZURES

  - Typical
  - Atypical
- Generalized tonic-clonic
- Tonic
- Clonic
- Myoclonic
- Atonic
- Infantile spasms

Myoclonic

Atonic

Infantile spasms

UNCLASSIFIED SEIZURES

Infants with benign myoclonic epilepsy have a more favorable outlook than patients with infantile spasms. Similarly, a school-aged child who has benign partial epilepsy with centrotemporal spikes (rolandic epilepsy) has an excellent prognosis and is unlikely to require a prolonged course of anticonvulsants. Clinical classification of seizures may be difficult because the manifestations of different seizure types may be similar. For example, the clinical features of a child with absence seizures may be almost identical to those of another patient with complex partial epilepsy. An EEG is a useful adjunct to the classification of epilepsy because of the variability of seizure expressivity in this age group. A classification combining the clinical description of the seizure with the EEG findings has improved the delineation of childhood epilepsy (Box 586–1).

Epilepsy in children has also been classified by syndrome. Using the age at onset of seizures, cognitive development and neurologic examination, description of seizure type, and EEG findings, including the background rhythm, it has been possible to classify approximately 50% of childhood seizures into specific syndromes. The *syndromic* classification of seizures provides a distinct advantage over previous classifications by improving management with appropriate anticonvulsant medication, identifying potential candidates for epilepsy surgery, and providing patients and families with a reliable and accurate prognosis. Examples of epilepsy syndromes include infantile spasms (West syndrome), benign myoclonic epilepsy of infancy, the Lennox-Gastaut syndrome, febrile convulsions, Landau-Kleffner syndrome, benign childhood epilepsy with centrotemporal spikes (rolandic epilepsy), Rasmussen encephalitis, juvenile myoclonic epilepsy (Janz syndrome), and Lafora disease (progressive myoclonic epilepsy).

586.3 Partial Seizures

Partial seizures account for a large proportion of childhood seizures, up to 40% in some series. Partial seizures may be classified as *simple* or *complex*; consciousness is maintained with simple seizures and is impaired in patients with complex seizures.

Simple Partial Seizures (SPS).

Motor activity is the most common symptom of SPS. The movements are characterized by asynchronous clonic or tonic movements, and they tend to involve the face, neck, and extremities. *Versive seizures* consisting of head turning and conjugate eye movements are particularly common in SPS. Automatisms do not occur with SPS, but some patients complain of aura (e.g., chest discomfort and headache), which may be the only manifestation of a seizure. Children have difficulty in describing aura and often refer to it as “feeling funny” or “something crawling inside me.” The average seizure persists for 10–20?sec. *The distinguishing characteristic of SPS is that the patients remain conscious and may verbalize during the seizure. Furthermore, no postictal phenomenon follows the event*. SPS may be confused with tics; however, *tics* are characterized by shoulder shrugging, eye blinking, and facial grimacing and primarily involve the face and shoulders (see Chapter 21). Tics can be briefly suppressed, but partial seizures cannot be controlled. The EEG may show spikes or sharp waves unilaterally or bilaterally or a multifocal spike pattern in patients with SPS.

Complex Partial Seizures (CPS).

A CPS may begin with a simple partial seizure with or without an aura, followed by impaired consciousness; conversely, the onset of the CPS may coincide with an altered state of consciousness. An *aura* consisting of vague, unpleasant feelings, epigastric discomfort, or fear is present in approximately one third of children with SPS and CPS. *The presence of an aura always indicates a focal onset of the seizure*. Because partial seizures are difficult to document in infants and children, the frequency of their association with CPS may be underestimated. Impaired consciousness in infants and children

---

is difficult to appreciate. There may be a brief blank stare or a sudden cessation or pause in activity that is frequently overlooked by the parent. Furthermore, the child is unable to communicate or to describe the periods of impaired consciousness in most

cases. Finally, the periods of altered consciousness may be brief and infrequent, and only an experienced observer or an EEG may be able to identify the abnormal event.

Automatisms are a common feature of CPS in infants and children, occurring in approximately 50–75% of cases; the older the child, the greater is the frequency of automatisms. Automatisms develop after the loss of consciousness and may persist into the postictal phase, but they are not recalled by the child. The automatic behavior observed in infants is characterized by alimentary automatisms, including lip smacking, chewing, swallowing, and excessive salivation. These movements can represent normal infant behavior and are difficult to distinguish from the automatisms of CPS. Prolonged and repetitive alimentary automatisms associated with a blank stare or with a lack of responsiveness almost always indicate CPS in an infant. Automatic behavior in older children consists of semi-purposeful, incoordinated, and unplanned gestural automatisms, including picking and pulling at clothing or bed sheets, rubbing or caressing objects, and walking or running in a nondirective, repetitive, and often fearful fashion.

Spreading of the epileptiform discharge during CPS can result in secondary generalization with a tonic-clonic convulsion. During the spread of the ictal discharge throughout the hemisphere, contralateral versive turning of the head, dystonic posturing, and tonic or clonic movements of the extremities and face including eye blinking may be noted. The average duration of a CPS is 1–2?min, which is considerably longer than an SPS or an absence seizure.

CPSs are associated with interictal EEG anterior temporal lobe sharp waves or focal spikes, and multifocal spikes are a frequent finding. Approximately 20% of infants and children with CPS have a normal routine interictal EEG. In these patients, a sleep-deprived EEG study, zygomatic leads during EEG, prolonged EEG recording, or video EEG study of the hospitalized patient weaned from anticonvulsants are techniques that can be used to increase the identification of spikes and sharp waves (Fig. 586–1*A*). In addition, some children with CPS have interictal sharp waves or spikes originating from the frontal, parietal, or occipital lobes. Radiographic studies including CT scanning and especially MRI are most likely to identify an abnormality in the temporal lobe of a child with CPS. These lesions include mesial temporal sclerosis, hamartoma, postencephalitic gliosis, subarachnoid cysts, infarction, arteriovenous malformations, and slow-growing glioma.

Benign Partial Epilepsy with Centrotemporal Spikes (BPEC).

BPEC is a common type of partial epilepsy in childhood and has an excellent prognosis. The clinical features, EEG findings (rolandic foci), and lack of a neuropathologic lesion are characteristic and readily separate BPEC from CPS. BPEC occurs between the ages of 2 and 14 yr and has a peak age of onset of 9–10 yr. The disorder occurs in normal children with an unremarkable history and

Figure 586.3-1 *A,* An EEG of partial seizures: (i) spike discharges from the left temporal lobe (*arrow*) in a patient with CPS, (ii) left parietal central spikes (*arrow*) characteristic of BPEC. *B,* Representative EEGs of generalized seizures: (i) 3/sec spike and wave discharge of absence seizures with normal background activity, (ii) complex myoclonic epilepsy (Lennox-Gastaut syndrome) with interictal slow spike waves, (iii) juvenile myoclonic epilepsy showing 6/sec spike and waves enhanced by photic stimulation, and (iv) hypsarrhythmia with an irregular high-voltage spike and wave activity.

normal neurologic examination. There is often a positive family history of epilepsy. The seizures are usually partial, and motor signs and somatosensory symptoms are often confined to the face. Oropharyngeal symptoms include tonic contractions and paresthesias of the tongue, unilateral numbness of the cheek (particularly along the gum), guttural noises, dysphagia, and excessive salivation. Unilateral tonic-clonic contractures of the lower face frequently accompany the oropharyngeal symptoms, as do clonic movements or paresthesias of the ipsilateral extremities. Consciousness may be intact or impaired, and the partial seizure may proceed to secondary generalization.

Approximately 20% of children experience only one seizure, the majority have infrequent seizure, and about one fourth have repeated clusters of seizures. BPEC occurs during sleep in 75% of patients, whereas CPS tends to be observed during waking hours. The EEG pattern is diagnostic for BPEC and is characterized by a repetitive spike focus localized in the centrotemporal or rolandic area with normal background activity (see Fig. 586–1*A*). Anticonvulsants are necessary for patients who have frequent seizures but should not be prescribed automatically after the initial convulsion. Carbamazepine is the preferred drug, which is continued for at least 2 yr or until 14–16 yr of age, when spontaneous remission of BPEC usually occurs.

Rasmussen Encephalitis.

This subacute inflammatory encephalitis is one cause of *epilepsia partialis continua*. A nonspecific febrile illness may have preceded the onset of focal seizures, which may be frequent or continuous. The onset is usually before age 10 yr. Sequelae include hemiplegia, hemianopia, and aphasia. The EEG reveals diffuse paroxysmal activity with a slow background. The disease is progressive and potentially lethal but more often becomes self-limited with significant neurologic deficits. The disease may be due to autoantibodies that bind to and stimulate the glutamate receptors. Studies have identified cytomegalovirus in several surgical specimens of patients with Rasmussen encephalitis.

586.4 Generalized Seizures

Absence Seizures.

Simple (typical) absence (petit mal) seizures are characterized by a sudden cessation of motor activity or speech with a blank facial expression and flickering of the eyelids. These seizures, which are uncommon before age 5 yr, are more prevalent in girls, they are never associated with an aura, they rarely persist longer than 30?sec, and they are not associated with a postictal state. These features tend to differentiate absence seizures from complex partial seizures. Children with absence seizures may experience countless seizures daily, whereas complex partial seizures are usually less frequent. Patients do not lose body tone, but their head may fall forward slightly. Immediately after the seizure, patients resume preseizure activity with no indication of postictal impairment. Automatic behavior frequently accompanies simple absence seizures. Hyperventilation for 3–4?min routinely produces an absence seizure. The EEG shows a typical 3/sec spike and generalized wave discharge (see Fig. 586–1*B*). Complex (atypical) absence seizures have associated motor components consisting of myoclonic movement of the face, fingers, or extremities and, on occasion, loss of body tone. These seizures produce atypical EEG spike and wave discharges at 2–2.5/sec.

Generalized Tonic-Clonic Seizures.

These seizures are extremely common and may follow a partial seizure with a focal onset (second generalization) or occur de novo. They may be associated with an aura, suggesting a focal origin of the epileptiform discharge. It is important to inquire about the presence of an aura, because its presence and site of origin may indicate the area of pathology. Patients suddenly lose consciousness and in some cases emit a shrill, piercing cry. Their eyes roll back, their entire body musculature undergoes tonic contractions, and they rapidly become cyanotic in association with apnea. The clonic phase of the seizure is heralded by rhythmic clonic contractions alternating with relaxation of all muscle groups. The clonic phase slows toward the end of the seizure, which usually persists for a few minutes, and patients often sigh as the seizure comes to an abrupt stop. During the seizure, children may bite their tongue but rarely vomit. Loss of sphincter control, particularly the bladder, is common during a generalized tonic-clonic seizure.

Tight clothing and jewelry around the neck should be loosened, the patient should be placed on one side, and the neck and jaw should be gently hyperextended to enhance breathing. The mouth should not be opened forcibly by an object or by a finger because the patient's teeth may be dislodged and aspirated, or significant injury to the oropharyngeal cavity may result. Postictally, children initially are semicomatose and typically remain in a deep sleep from 30?min to 2?hr. If patients are examined during the seizure or immediately postictally, they may demonstrate truncal ataxia, hyperactive deep tendon reflexes, clonus, and a Babinski reflex. The postictal phase is often associated with vomiting and an intense bifrontal headache.

Idiopathic seizure is a term applied when the cause of a generalized seizure cannot be ascertained. Many factors are known to precipitate generalized tonic-clonic seizures in children, including low-grade fever associated with infections, excessive fatigue or emotional stress, and various drugs including psychotropic medications, theophylline, and methylphenidate, particularly if the seizures are poorly controlled by anticonvulsant drugs.

Myoclonic Epilepsies of Childhood.

This disorder is characterized by repetitive seizures consisting of brief, often symmetric muscular contractions with loss of body tone and falling or slumping forward, which has a tendency to cause injuries to the face and mouth. Myoclonic epilepsies include a heterogeneous group of conditions with multiple causes and variable outcomes. However, at least five distinct subgroupings can be identified; these represent the broad spectrum of myoclonic epilepsies in the pediatric population.

BENIGN MYOCLONUS OF INFANCY.

Benign myoclonus begins during infancy and consists of clusters of myoclonic movements confined to the neck, trunk, and extremities. The myoclonic activity may be confused with infantile spasms; however, the EEG is normal in patients with benign myoclonus. The prognosis is good, with normal development and the cessation of myoclonus by 2 yr of age. An anticonvulsant is not indicated.

TYPICAL MYOCLONIC EPILEPSY OF EARLY CHILDHOOD.

Children who develop typical myoclonic epilepsy are near normal before the onset of seizures, with an unremarkable pregnancy, labor, and delivery and intact developmental milestones. The mean age of onset is approximately 2 yr, but the range spreads from 6 mo to 4 yr. The frequency of myoclonic seizures varies; they may occur several times daily, or children may be seizure-free for weeks. A few patients have febrile convulsions or generalized tonic-clonic afebrile seizures that precede the onset of myoclonic epilepsy. Approximately half of patients occasionally have tonic-clonic seizures in addition to the myoclonic epilepsy. The EEG shows fast spike wave complexes of 2.5?Hz or greater and a normal background rhythm in most cases. At least one third of the children have a positive family history of epilepsy, which suggests a genetic etiology in some cases. The long-term outcome is relatively favorable. Mental retardation develops in the minority, and more than 50% are seizure-free several years later. However, learning and language problems and emotional and behavioral disorders occur in a significant number of these children and require prolonged follow-up by a multidisciplinary team.

COMPLEX MYOCLONIC EPILEPSIES.

These consist of a heterogeneous group of disorders with a uniformly poor

prognosis. Focal or generalized tonic-clonic seizures beginning during the 1st year of life typically antedate the onset of myoclonic epilepsy. The generalized seizure is often associated with an upper respiratory tract infection and a low-grade fever and frequently develops into status epilepticus. Approximately one third of these patients have evidence of delayed developmental milestones. A history of hypoxic-ischemic encephalopathy in the perinatal period and the finding of generalized upper motor neuron and extrapyramidal signs with microcephaly constitute a common pattern among these children. A family history of epilepsy is much less prominent in this group compared with typical myoclonic epilepsy.

Some children display a combination of frequent myoclonic and tonic seizures, and when interictal slow spike waves are evident in the EEG, the seizure disorder is classified as the *Lennox-Gastaut syndrome.* This syndrome is characterized by the triad of intractable seizures of various types, a slow spike wave EEG during the awake state, and mental retardation. Patients with complex myoclonic epilepsy routinely have interictal slow spike waves and are refractory to anticonvulsants (see Fig. 586–1*B*). The seizures are persistent, and the frequency of mental retardation and behavioral problems is approximately 75% of all patients. Treatment with valproic acid or benzodiazepines may decrease the frequency or intensity of the seizures. The ketogenic diet should be considered for patients whose seizures are refractory to anticonvulsants.

JUVENILE MYOCLONIC EPILEPSY (JANZ SYNDROME).

Juvenile myoclonic epilepsy usually begins between the ages of 12 and 16 yr and accounts for approximately 5% of the epilepsies. A gene locus has been identified on chromosome 6p21. Patients note frequent myoclonic jerks on awakening, making hair combing and tooth brushing difficult. As the myoclonus tends to abate later in the morning, most patients do not seek medical advice at this stage and some deny the episodes. A few years later, early morning generalized tonic-clonic seizures develop in association with the myoclonus. The EEG shows a 4–6/sec irregular spike and wave pattern, which is enhanced by photic stimulation (see Fig. 586–1*B*). The neurologic examination is normal, and the majority respond dramatically to valproate, which is required lifelong. Discontinuance of the drug causes a high rate of recurrence of seizures.

PROGRESSIVE MYOCLONIC EPILEPSIES.

This heterogeneous group of rare genetic disorders uniformly has a grave prognosis. These conditions include Lafora disease, myoclonic epilepsy with ragged-red fibers (MERRF) (see Chapter 591.2), sialidosis type 1 (see Chapter 592.4), ceroid lipofuscinosis (see Chapter 592.2), juvenile neuropathic Gaucher disease, and juvenile neuroaxonal dystrophy.

Lafora disease presents in children between 10 and 18 yr with generalized tonic-clonic seizures. Ultimately, myoclonic jerks appear; these become more apparent and constant with progression of the disease. Mental deterioration is a characteristic feature and becomes evident within 1 yr of the onset of seizures. Neurologic abnormalities, particularly cerebellar and extrapyramidal signs, are prominent findings. The EEG shows polyspike-wave discharges, particularly in the occipital region, with progressive slowing and a disorganized background. The myoclonic jerks are difficult to control, but a combination of valproic acid and a benzodiazepine (e.g., clonazepam) is effective in controlling the generalized seizures. Lafora disease is an autosomal recessive disorder, and the diagnosis may be established by examination of a skin biopsy specimen for characteristic periodic acid-Schiff positive inclusions, which are most prominent in the eccrine sweat gland duct cells. The gene for Lafora disease is located on 6p24 and it encodes a protein, tyrosine phosphatase.

Infantile Spasms.

Infantile spasms usually begin between the ages of 4 and 8 mo and are characterized by brief symmetric contractions of the neck, trunk, and extremities. There are at least three types of infantile spasms: flexor, extensor, and mixed. *Flexor spasms* occur in clusters or volleys and consist of sudden flexion of the neck, arms, and legs onto the trunk, whereas *extensor spasms* produce extension of the trunk and extremities and are the least common form of infantile spasm. *Mixed infantile spasms*, consisting of flexion in some volleys and extension in others, is the most common type of infantile spasm. Clusters or volleys of seizures may persist for minutes, with brief intervals between each spasm. A cry may precede or follow an infantile spasm, accounting for the confusion with colic in a few cases. The spasms occur during sleep or arousal but have a tendency to develop while patients are drowsy or immediately on awakening. The EEG that is most commonly associated with infantile spasms is referred to as *hypsarrhythmia*, which consists of a chaotic pattern of high-voltage, bilaterally asynchronous, slow-wave activity (see Fig. 586–1*B*), or a modified hypsarrhythmia pattern.

Infantile spasms are typically classified into two groups: *cryptogenic* and *symptomatic*. A child with cryptogenic infantile spasms has an uneventful pregnancy and birth history as well as normal developmental milestones before the onset of seizures. The neurologic examination and the CT and MRI scans of the head are normal, and there are no associated risk factors. Approximately 10–20% of infantile spasms are classified as cryptogenic, and the remainder are classified as symptomatic. Symptomatic infantile spasms are related directly to several prenatal, perinatal, and postnatal factors. Prenatal and perinatal factors include hypoxic-ischemic encephalopathy with periventricular leukomalacia, congenital infections, inborn errors of metabolism, neurocutaneous syndromes such as tuberous sclerosis, cytoarchitectural abnormalities including lissencephaly and schizencephaly, and prematurity. Postnatal conditions include CNS infections, head trauma (especially subdural hematoma and intraventricular hemorrhage), and hypoxic-ischemic encephalopathy. The fact that infantile spasms and immunizations often occur simultaneously around 6 mo of age is a coincidence of timing rather than a cause and effect of any immunization antigen.

Infants with cryptogenic infantile spasms have a good prognosis, whereas those with

the symptomatic type have an 80–90% risk of mental retardation. The underlying CNS disorder has a major role in the neurologic outcome. Several theories have been advanced with regard to the pathogenesis of infantile spasms, including dysfunction of the monoaminergic neurotransmitter system in the brainstem, derangement of neuronal structures in the brainstem, and an abnormality of the immune system. One hypothesis implicates corticotropin-releasing hormone (CRH), a putative neurotransmitter, metabolized in the inferior olive. CRH acts on the pituitary to enhance the release of adrenocorticotropic hormone (ACTH); ACTH and glucocorticoids suppress the metabolism and secretion of CRH by a feedback mechanism. It is proposed that specified stresses or injury to an infant during a critical period of neurodevelopment causes CRH overproduction, resulting in neuronal hyperexcitability and seizures. The number of CRH receptors reaches a maximum in an infant's brain followed by spontaneous reduction with age, perhaps accounting for the eventual resolution of infantile spasms, even without therapy. Exogenous ACTH and glucocorticoids suppress CRH synthesis, which may account for their effectiveness in treating infantile spasms. Therapy for infantile spasms is discussed in the section on treatment.

Landau-Kleffner Syndrome (LKS).

This is a rare condition of unknown cause. It is more common in boys and has a mean onset of 51/2 yr. LKS is often confused with autism, in that both conditions are associated with a loss of language function. LKS is characterized by loss of language skills in a previously normal child. At least 70% have an associated seizure disorder. Language regression may be sudden or the speech loss protracted.

The aphasia may be primarily receptive or expressive, and auditory agnosia may be so severe that the child is oblivious to everyday sounds. Hearing is normal, but behavioral problems, including irritability and poor attention span, are particularly common. Formal testing often shows normal performance and visual-spatial skills despite poor language. The seizures are of several types, including focal or generalized tonic-clonic, atypical absence, partial complex, and occasionally myoclonic. High-amplitude spike and wave discharges predominate and tend to be bitemporal, but they can be multifocal or generalized. In the evolutionary stages of the condition, the EEG findings may be normal. The spike discharges are always more apparent during non–rapid eye movement (REM) sleep; thus, a child suspected of LKS should have an EEG during sleep, particularly if the awake record is normal. If the sleep EEG is normal but a high index of suspicion for the diagnosis of LKS continues, the child should be referred to a tertiary pediatric epilepsy center for prolonged EEG recording and specific neuroimaging studies. CT and MRI studies typically yield normal results, and positron-emission tomography (PET) scans have demonstrated either unilateral or bilateral hypometabolism or hypermetabolism. Microscopic examination of surgical specimens has shown minimal gliosis but no evidence of encephalitis.

Valproic acid is the anticonvulsant of choice; however, some children require a combination of valproic acid and clobazam to control their seizures. If the seizures and aphasia persist, a trial of steroids should be considered. One recommended schedule consists of oral prednisone, 2?mg/kg/24?hr for 1 mo, tapered to 1?mg/kg/24?hr for an additional month. With clinical improvement, the prednisone is reduced further to 0.5?mg/kg/24?hr for up to 6–12 mo. It is imperative to initiate speech therapy and maintain treatment for several years, because improvement in language function occurs over a prolonged period. Some centers advocate an operative procedure—subpial transection—when medical management fails. Methylphenidate should be considered for patients with severe hyperactivity and inattention. Seizures, if poorly controlled, may be potentiated by methylphenidate; however, anticonvulsants are usually protective. Intravenous immunoglobulin may be helpful in LKS. Some children experience a recurrence of aphasia and seizures after apparent recovery. Most children with LKS have a significant abnormality of speech function during adulthood. The onset of LKS at an early age (<2 yr) uniformly tends to be associated with a poor prognosis for recovery of speech.

586.5 Mechanisms of Seizures

Although the precise mechanisms of seizures are unknown, several physiologic factors are responsible for the development of a seizure. To initiate a seizure, there must be a group of neurons that are capable of generating a significant burst discharge and a GABAergic inhibitory system. Seizure discharge transmission ultimately depends on excitatory glutamatergic synapses. Evidence suggests that excitatory amino acid neurotransmitters (glutamate, aspartate) may have a role in producing neuronal excitation by acting on specific cell receptors. Seizures may arise from areas of neuronal death, and these regions of the brain may promote development of novel hyperexcitable synapses that can cause seizures. For example, lesions in the temporal lobe (including slow-growing gliomas, hamartomas, gliosis, and arteriovenous malformations) cause seizures, and when the abnormal tissue is removed surgically, the seizures are likely to cease. Further, convulsions may be produced in experimental animals by the phenomenon of *kindling*. In this model, repeated subconvulsive stimulation of the brain (e.g., amygdala) ultimately leads to a generalized convulsion. Kindling may be responsible for the development of epilepsy in humans after an injury to the brain. In humans, it has been proposed that recurrent seizure activity from an abnormal temporal lobe may produce seizures in the contralateral normal temporal lobe by transmission of the stimulus via the corpus callosum.

Seizures are more common in infants and in immature experimental animals. Certain seizures in the pediatric population are age specific (e.g., infantile spasms); this observation suggests that the underdeveloped brain is more susceptible to specific seizures than is the brain of an older child or adult. Genetic factors account for at least 20% of all cases of epilepsy. Using linkage analyses, the chromosomal location of several familial epilepsies has been identified, including benign neonatal convulsions (20q and 8q), juvenile myoclonic epilepsy (6p), and progressive myoclonic epilepsy (21q22.3). The genetic defect of benign familial neonatal convulsions has been characterized by the identification of submicroscopic deletion of chromosome 20q13.3. Study of the cDNAs spanning the deleted region identified one encoding a novel voltage-gated potassium channel, $KCNQ_2$. Furthermore, the substantia nigra has an integral role in the development of generalized seizures. Electrographic seizure activity spreads within the substantia nigra, causing an increase in uptake of 2-deoxyglucose in adult animals, but there is little or no metabolic activity within the substantia nigra when immature animals have a convulsion. It has been proposed that the functional immaturity of the substantia nigra may have a role in the increased seizure susceptibility of the immature brain. Additionally, the ?-aminobutyric acid (GABA)-sensitive substantia nigra pars reticulata neurons play a part in preventing seizures. It is likely that substantia nigra outflow tracts modulate and regulate seizure dissemination but are not responsible for the onset of seizures.

Use of the EEG to Diagnose Epilepsy.

The investigation of a seizure depends on many factors, including the age of the patient, the type and frequency of the seizure, and the presence or absence of neurologic findings and constitutional symptoms. Demonstration of paroxysmal discharges on the EEG during a clinical seizure is diagnostic of epilepsy, but seizures rarely occur in the EEG laboratory. A normal EEG does not preclude the diagnosis of epilepsy, because the interictal recording is normal in approximately 40% of patients. Activation procedures, including hyperventilation, eye closure, photic stimulation, and, when indicated, sleep deprivation and special electrode placement (e.g., zygomatic leads) substantially increase the positive yield. Seizure discharges are more likely to be recorded in infants and children than in adolescents or adults. Patients who are taking an anticonvulsant and who are scheduled for a routine EEG should not have the medication decreased or discontinued before the study, because status epilepticus could result.

Prolonged EEG monitoring with simultaneous closed-circuit video recording is reserved for complicated cases of protracted and unresponsive seizures. It provides an invaluable method for recording ictal seizure events that are rarely obtained during routine EEG studies. This technique is extremely helpful in the classification of seizures because it can accurately determine the location and frequency of seizure discharges while recording alterations in the level of consciousness and the presence of clinical signs. Patients with pseudoseizures can be readily distinguished from those with true epilepsy, and seizure type (e.g., complex partial vs generalized) can be more precisely identified. Determination of seizure type is critical in the investigation of a child who may be a candidate for epilepsy surgery.

586.6 Treatment of Epilepsy

The first step in the management of epilepsy is to ensure that the patient has a seizure disorder and not a condition that mimics epilepsy (see Chapter 587). It is sometimes difficult to be certain about the cause of a paroxysmal event in a normal child. A

negative result on a neurologic examination and EEG usually supports the approach of watchful waiting rather than administration of an anticonvulsant. The true cause of the paroxysmal disorder eventually becomes apparent. Although there is not uniform agreement, most would concur that antiepileptics should be withheld from a previously healthy child with the first afebrile convulsion if there is a negative family history, normal results of an examination and EEG, and a cooperative and compliant family. Approximately 70% of these children will not experience another convulsion. Approximately 75% of those patients with two or three unprovoked seizures have additional seizures. A recurrent seizure, particularly if it occurs in close proximity to the first seizure, is an indication to begin an anticonvulsant. Figure 586–2 suggests an approach to a child with a suspected seizure disorder.

The second step involves choosing an anticonvulsant. The drug of choice depends on the classification of the seizure, determined by the history and EEG findings. The goal for every patient should be the use of only one drug with the fewest possible side effects for the control of seizures. The drug is increased

Figure 586.6-2 An approach to the child with a suspected convulsive disorder.

slowly until seizure control is accomplished or until undesirable side effects develop. The child's serum anticonvulsant level should be monitored during this stage, and the dose should be altered accordingly. Table 586–1 summarizes the common antiepileptic drugs used in childhood epilepsy and highlights the recommended daily dose, therapeutic serum levels, and common side effects. A suggested loading dose is indicated for drugs that are useful for the treatment of status epilepticus. Physicians should be familiar with the pharmacokinetics of the anticonvulsant and its toxic actions and should monitor the child on a regular basis to gauge the seizure control while watching for unwanted side effects.

Routine serum monitoring of anticonvulsant levels is not recommended because the practice is not cost effective. There are several important indications for anticonvulsant drug monitoring: (1) at the onset of anticonvulsant therapy to confirm that the drug level is within the therapeutic range; (2) for noncompliant patients and families; (3) at the time of status epilepticus; (4) during accelerated growth spurts; (5) for patients on polytherapy, especially valproic acid, phenobarbital, and lamotrigine

TABLE 586.6-1 -- **Common Anticonvulsant Drugs**

Drug	Seizure Type	Oral Dose	Loading Dose (IV)	Therapeutic Serum Level μg/ mL)
Carbamazepine (Tegretol)	Generalized tonic-clonic Partial	Begin 10?mg/ kg/ 24?hr Increase to 20 – 30?mg/ kg/ 24?hr tid	—	8 – 12
Clobazam (Frisium)	Adjunctive therapy when seizures poorly controlled	0.25 – 1?mg/ kg/ 24?hr bid or tid	—	—
Clonazepam (Rivotril)	Absence Myoclonic Infantile spasms Partial Lennox-Gastaut Akinetic	Children < 30?kg: Begin 0.05?mg/ kg/ 24?hr Increase by 0.05?mg/ kg/ wk Maximum 0.2?mg/ kg/ 24?hr bid or tid Children > 30?kg: 1.5?mg/ kg/ 24?hr tid, not to exceed 20?mg/ 24?hr	—	> 0.013
Ethosuximide (Zarontin)	Absence May increase tonic-clonic seizures	Begin 20?mg/ kg/ 24?hr Increase to maximum of 40?mg/ kg/ 24?hr or 1.5?g/ 24?hr, whichever is less	—	40 – 100

Gabapentin (Neurontin)	Adjuntive therapy when seizures poorly controlled	Children: 20 – 50?mg/ kg/ 24?hr tid Adolescence: 900 – 3,600?mg/ 24?hr tid	—	Not necessary to monitor	
Lamotrigine (Lamictal)	Adjunctive therapy when seizures poorly controlled Broad-spectrum anticonvulsant activity in various seizure types including: complex partial, absence, myoclonic, clonic, tonic-clonic, and Lennox-Gastaut	Individualized based on age and additional anticonvulsants(see Chapter 586.6)	—	—	
Nitrazepam (Mogadon)	Absence Myoclonic Infantile spasms	Begin 0.2?mg/ kg/ 24?hr Increase slowly to 1?mg/ kg/ 24?hr tid	—	—	
Paraldehyde	Generalized status epilepticus	Make a 5% solution by adding 1.75?mL of paraldehyde to D5W with total volume of 35?mL	150 – 200?mg/ kg Maintenance, 20?mg/ kg/ hr	10 – 40	
Phenobarbital	Generalized tonic-clonic Partial Status epilepticus	3 – 5?mg/ kg/ 24?hr bid	20?mg/ kg 20 – 30?mg/ kg in the neonate	15 – 40	
Phenytoin (Dilantin)	Generalized tonic-clonic Partial Status epilepticus	3 – 9?mg/ kg/ 24?hr bid	20?mg/ kg	10 – 20	
Primidone (Mysoline)	Generalized tonic-clonic Partial	Children < 8 yr: 10 – 25?mg/ kg/ 24?hr tid or qid Children > 8 yr: usual maintenance dose, 750 – 1,500?mg/ 24?hr tid or qid	—	5 – 12	
Topiramate (Topimax)	Adjunctive therapy for poorly controlled seizures Refractory complex partial seizures	1 – 9?mg/ kg/ 24?hr bid	—	—	
Tiagabine (Gabitril)	Adjunctive therapy for complex partial seizures	Average dose, 6?mg tid	—	—	
Valproic acid (Depakene, Epival)	Generalized tonic-clonic Absence Myoclonic Partial Akinetic	Begin 10?mg/ kg/ 24?hr Increase by 5 – 10?mg/ kg/ wk Usual dose, 30 – 60?mg/ kg/ 24?hr tid or qid	Intravenous preparation now available Studies in children under way	50 – 100	

Vigabatrin (Sabril)	Infantile spasms Adjunctive therapy for poorly controlled seizures	Begin 30?mg/ kg/ 24?hr once daily or bid Maintenance dose, 30 – 100?mg/ kg/ 24?hr once daily or bid	—	—	

SIADH = syndrome of inappropriate secretion of antidiuretic hormone.

** Not available in the United States.*

because of drug interactions; (6) for uncontrolled seizures or seizures that have changed in type; (7) for symptoms and signs of drug toxicity (e.g., toxicity due to a metabolite of carbamazepine, carbamazepine-10,11 epoxide); (8) for patients with hepatic or renal disease; and (9) for children with cognitive or physical disabilities, especially those taking phenytoin, in whom toxicity may be difficult to evaluate. Good clinical judgment is more reliable in achieving seizure control than over-reliance on therapeutic drug monitoring.

There is controversy about whether routine blood tests (complete blood count [CBC], liver function studies) are indicated during anticonvulsant therapy. Because most serious adverse anticonvulsant drug reactions develop during the initial 2–3 mo of therapy, monthly blood screening for the first 3 mo is recommended. Subsequently, routine blood tests are ordered only when clinically indicated.

Anticonvulsants that are introduced during childhood may be required during adolescence and the childbearing years. Unfortunately, some anticonvulsants, including phenytoin, valproic acid, carbamazepine, and primidone, are associated with the occurrence of specific birth defects, including facial and limb anomalies and spinal dysraphism. Whether the teratogenic effect is secondary to the mother's epilepsy or the anticonvulsant medication is still debated. Meanwhile, the pediatrician should counsel the family about the possible relationship and should avoid prescribing an anticonvulsant to a pregnant patient unless it is absolutely necessary.

If complete seizure control is accomplished by an anticonvulsant, a minimum of 2 seizure-free years is an adequate and safe period of treatment for a patient with no risk factors. Prominent risk factors include age greater than 12 yr at onset, neurologic dysfunction (motor handicap or mental retardation), a history of prior neonatal seizures, and numerous seizures before control is achieved. In a child with complete seizure control for a minimum of 2 yr and low risk factors, the chance of recurrence is approximately 20–25%, particularly during the first 6 mo after discontinuation of the anticonvulsant. Those children with the best prognosis following anticonvulsant withdrawal are those with benign epilepsy with rolandic spikes and those with idiopathic generalized seizures. CPS and juvenile myoclonic seizures are more likely to recur. When the decision is made to discontinue the drug, the weaning process should occur for 3–6 mo, because abrupt withdrawal may cause status epilepticus.

Possible sites of action, dose, and side effects of anticonvulsants are noted in Figure 586–3 and Table 586–1 .

Benzodiazepines.

The benzodiazepines exert anticonvulsant activity by binding to a specific GABA site that enhances the opening frequency of the chloride channel without affecting open or burst duration (see Fig. 586–3). The drugs *diazepam* and *lorazepam* IV are used for initial management of status epilepticus. Rectal *diazepam* gel has been demonstrated to be an effective and safe treatment to abort episodes of acute repetitive seizures in children and is available as Diastat gel in 2.5, 5, and

Figure 586.6-3 Pharmacologic effects of antiepileptic drugs at $GABA_A$ receptor. GABA = ?-aminobutyric acid; GAD = glutamic acid decarboxylase; GABA-T = GABA transaminase. Barbiturates bind to ß-subunit of $GABA_A$ receptor to potentiate action of endogenous agonist GABA and prolong opening time of chloride ion channel. Benzodiazepines bind to an a-subunit of $GABA_A$ to potentiate action of GABA and increase frequency of opening of chloride ion channel. Vigabatrin irreversibly binds to GABA-transaminase to inhibit degradation of inhibitory neurotransmitter GABA. Tiagabine blocks uptake of synaptically released GABA into both presynaptic neurons and glial cells, allowing GABA to remain at site of action for longer periods. (From Leach JP, Brodie MJ: Tiagabine. *Lancet* 1998;351:203.)

10?mg doses for children. *Clonazepam* is useful for the management of the Lennox-Gastaut syndrome, myoclonic, akinetic, and absence seizures. The elimination half-life is 18–50?hr. Clonazepam may increase serum phenytoin concentrations when used together, and additional CNS depression may occur when combined with other CNS depressant drugs. Clonazepam is supplied in 0.5 and 2?mg tablets. *Nitrazepam* is useful for the management of myoclonic seizures. The elimination half-life is 18–57?hr. The drug may increase CNS depression when used with additional depressants. Nitrazepam is supplied in 5 and 10?mg tablets. *Clobazam* is indicated as adjunctive therapy for complex partial seizures. The half-life is 10–30?hr. Clobazam may increase the serum drug levels of carbamazepine, phenytoin, phenobarbital, and valproic acid when used concomitantly. Clobazam is supplied in 10?mg tablets.

Carbamazepine.

This drug is effective for the management of generalized tonic-clonic and partial seizures. Carbamazepine acts similarly to phenytoin by decreasing the sustained repetitive firing of neurons by blocking sodium-dependent channels and by decreasing depolarization-dependent calcium uptake. Significant leukopenia (<1,000 neutrophils/mL^3) and hepatotoxicity may rarely develop, particularly during the initial

3–4 mo of therapy. Therefore, a CBC with differential and AST and ALT levels should be obtained on a monthly basis during this period, although serious idiosyncratic drug reactions may develop despite normal liver function tests results and routine blood work. Subsequent laboratory testing is determined by the presence of adverse symptoms or signs. The parents should be informed of untoward drug effects and instructed to report them immediately to the physician. Erythromycin should be used cautiously with carbamazepine because the two drugs compete for metabolism by the liver. The plasma concentration of carbamazepine is lowered by phenytoin, phenobarbital, and valproic acid. Carbamazepine-10,11-epoxide, which is an active metabolite of carbamazepine, may produce toxicity despite therapeutic carbamazepine levels, particularly when valproic acid is added to the drug regimen. Hyponatremia has also been reported as a side effect of this drug. Carbamazepine is supplied in suspension, 20?mg/mL; chew tabs, 100 and 200?mg tablets; and controlled release (CR) form, 200 and 400?mg tablets. The half-life is 8–20?hr, and the drug should be given two or three times daily.

Ethosuximide.

Ethosuximide provides its anticonvulsant action by blocking calcium channels associated with thalamocortical circuitry. Ethosuximide is an effective drug for the management of typical absence epilepsy and has a half-life of 60?hr. When used with phenobarbital or primidone, ethosuximide may reduce the serum levels of those anticonvulsants. Ethosuximide is supplied in syrup, 50?mg/mL, and in 250?mg capsules.

Gabapentin.

This anticonvulsant is used as an add-on drug for patients with refractory complex partial and secondarily generalized tonic-clonic seizures. The mechanism of action results from binding of the drug to neuronal membranes (glutamate synapses) and increased brain GABA turnover. The plasma half-life of gabapentin is 5–7?hr. The drug is rapidly absorbed from the gastrointestinal tract, does not bind to plasma proteins, and is not metabolized. Gabapentin has no significant drug interactions and is relatively free of dose-related CNS adverse effects. Gabapentin is recommended for children 12 yr and older. Gabapentin is supplied in 100, 300, and 400?mg capsules.

Lamotrigine.

Lamotrigine is a phenyltriazine compound used as an add-on drug for the management of complex partial and generalized tonic-clonic seizures. Lamotrigine is effective as monotherapy for some children with the Lennox-Gastaut syndrome and generalized absence seizures. Pharmacologic studies suggest the drug acts at voltage-sensitive sodium channels to stabilize neuronal membranes and inhibit neuronal release, particularly glutamate. The plasma elimination half-life is 22–37?hr. In children, the recommended starting dose is 2?mg/kg/24?hr for 2 wk divided into two doses, followed by 5?mg/kg/24?hr for an additional 2 wk. The maintenance dose is 5–15?mg/kg/24?hr. If lamotrigine is added to valproate therapy, the starting dose of lamotrigine should be reduced to 0.5?mg/kg/24?hr because valproate inhibits the metabolism of lamotrigine. In this case, the maintenance dose of lamotrigine is 1–5?mg/kg/24?hr. The therapeutic serum level is 1–4?mg/L or 3.9–15.6?µmol/L.

Common side effects include nausea, headache, dizziness, blurred vision, diplopia, and ataxia. A maculopapular skin rash develops in about 3% of patients. The Stevens-Johnson syndrome, angioedema, or toxic epidermal necrolysis occasionally results, usually during the first month of therapy, especially in association with valproate. Because these skin disorders may be fatal, the anticonvulsants must be immediately discontinued. Lamotrigine is supplied in 25, 50, 100, and 200?mg tablets.

Phenobarbital and Primidone.

These are relatively safe anticonvulsants that are particularly useful for generalized tonic-clonic seizures. However, approximately 25% of children undergo severe behavioral changes on these drugs. Neurologically abnormal children are at greater risk. Furthermore, there is evidence that phenobarbital may adversely affect the cognitive performance of children treated on a long-term basis. Valproic acid interferes with the metabolism of phenobarbital, causing elevated phenobarbital plasma levels and toxicity despite the usual daily doses. Phenobarbital acts on the GABA receptor to increase the chloride channel open duration (see Fig. 586–3). The plasma half-life is 48–150?hr. Phenobarbital is supplied in an elixir, 4?mg/mL; tablets, 15, 30, 60, and 100?mg; and injectable, 30 and 120?mg/mL. Primidone is prepared in a suspension, 50?mg/mL, and in 125 and 250?mg tablets. The plasma half-life of primidone is 10–21?hr. Phenobarbital is prescribed twice daily, and primidone is prescribed three times a day. Routine blood tests are not indicated for these anticonvulsants.

Phenytoin.

Phenytoin acts by decreasing the sustained repetitive firing of single neurons by blocking sodium-dependent channels and decreasing depolarization-dependent calcium uptake. Phenytoin is used for primary and secondary generalized tonic-clonic seizures, partial seizures, and status epilepticus. The plasma half-life is 7–42?hr. Phenytoin has many drug interactions that may increase or decrease other concomitantly used anticonvulsants (see Table 586–1). Phenytoin is supplied in a suspension, 6 and 25?mg/mL; chewable tablets, 50?mg; capsules, 100?mg; and injectable, 100?mg/2?mL and 250?mg/5?mL. Fosphenytoin, a water-soluble prodrug of phenytoin for intramuscular or intravenous use, is available in a concentration of 75?mg/mL, equivalent to 50?mg/mL of phenytoin.

Tiagabine.

Tiagabine inhibits seizure activity by blocking reuptake of the neuroinhibitory transmitter GABA into neuronal and glial cells (see Fig. 586–3). The drug is effective in the management of complex partial seizures as an add-on drug. Tiagabine is supplied in 4, 12, 16, and 20?mg tablets.

Topiramate.

Topiramate produces anticonvulsant action by blocking voltage-dependent sodium channels. The drug is used as adjunctive therapy for refractory complex seizures with or without secondary generalization. The elimination half-life is 21?hr. Phenytoin, carbamazepine, and valproic acid may decrease the concentration of

topiramate. Topiramate is dispensed in 25, 100, and 200?mg tablets.

Valproic Acid.

Valproic acid is a broad-spectrum anticonvulsant. It acts by blocking voltage-dependent sodium channels and increases calcium-dependent potassium conductance. The elimination half-life is 6–16?hr. This drug is useful for the management of many seizure types, including generalized tonic-clonic, absence, atypical absence, and myoclonic seizures. It rarely induces behavioral changes but is associated with mild

---

gastrointestinal disturbances, alopecia, tremor, and hyperphagia. Two rare but serious side effects of valproate are a Reye-like syndrome and irreversible hepatotoxicity. A small number of children develop progressive lethargy and coma with elevated serum ammonia and decreased levels of serum carnitine. Valproic acid may block the metabolism of carnitine, producing the altered state of consciousness in these patients. Discontinuation of valproic acid leads to recovery over several days.

Another small group of patients, particularly children younger than 2 yr and having specific neurologic syndromes, who are treated with several anticonvulsants simultaneously, are at significant risk (1:800) for developing an idiosyncratic potentially fatal hepatotoxic syndrome, characterized by abdominal pain, anorexia, weight loss, and retching within a few weeks to months of beginning valproate therapy. These patients have normal results of liver function studies during the initial stages; thus, significant and persistent gastrointestinal symptoms are cause for alarm during the initial few months of valproate therapy. If reduction in the valproate dose does not provide immediate relief, the physician should discontinue the drug. To decrease the risk of fatal hepatotoxicity, a series of screening tests for an underlying metabolic disorder is indicated for a child younger than 2 yr and having a seizure disorder of unknown cause, before initiation of valproic acid therapy. The tests include determinations of serum ammonium, amino acids, blood gases, a lactate-pyruvate ratio, urinary organic acids, and free and total serum carnitine. The incidence of fatal valproic acid–induced hepatotoxicity has decreased dramatically in recent years due to less use of the drug in epileptic children younger than 2 yr and the knowledge that monotherapy is much less likely to result in fatal liver disease.

Valproic acid also may cause a decrease in serum-free carnitine levels by inhibition of plasmalemmal carnitine uptake. Some studies suggest that carnitine deficiency is a major cause of valproate hepatotoxicity and that supplementation with L-carnitine, 50–100?mg/kg/24?hr, may prevent this fatal complication. Until further data are available, it is recommended that L-carnitine supplementation be provided to those children at greatest risk for hepatotoxicity (see earlier). In older children on valproic acid therapy, L-carnitine supplementation should be administered if there are clinical symptoms suggestive of carnitine deficiency (weakness, lethargy, hypotonia) or if a significant decrease in the serum-free carnitine levels is measured on a periodic basis. Valproic acid is available in a syrup, 50?mg/mL; capsules, 250 and 500?mg; and tablets, 125, 250, and 500?mg.

Depakote sprinkle capsules (divalproex sodium, a stable co-ordination compound composed of sodium valproate and valproic acid) are useful for children who are unable to tolerate valproate suspension, tablets, or capsules. The contents of the Depakote capsule are sprinkled onto soft food that does not require chewing. Depakote sprinkle capsules are supplied in 125?mg capsules.

Vigabatrin.

Vigabatrin acts by binding to the degradative enzyme GABA transaminase receptor, causing an increase in GABA levels and inhibition of neurotransmission (see Fig. 586–3). The drug is effective in the management of infantile spasms, particularly in children with tuberous sclerosis. Vigabatrin is also useful as adjunctive therapy for poorly controlled seizures. The plasma half-life is 5–8?hr. Vigabatrin may cause a reduction in plasma phenobarbital and phenytoin levels. Visual field constrictions have also been reported. The drug is supplied in 500?mg tablets and 500?mg sachets.

Leviractam.

Leviracetam acts by an unknown mechanism and is indicated for use as an adjunctive treatment for partial seizures. Plasma half-life is approximately 8?hr. It is supplied in 250, 500, and 750?mg tablets as Keppra.

Oxcarbazepine.

Oxcarbazepine has some similarity to carbamazepine in its action and is useful as an adjunctive treatment for partial seizures in adults and children. The half-life of the drug is 2?hr, whereas that of its major metabolite, 10-mono-hydroxy oxcarbazepine (MHD), is 9?hr. A total of 30% of patients with allergic reactions to carbamazepine also react to oxcarbazepine; hyponatremia occurs in 2.5% of patients. Oxcarbazepine is supplied as Trileptal in tablets, 150, 300, and 600?mg, and in suspension, 300?mg/5?mL.

Zonisamide.

Zonisamide is useful as an adjunctive treatment for partial seizures and may also be useful for myoclonic syndromes, but its mechanism of action is unclear. As a single drug, its half-life is 60?hr; half-life is shortened to 30?hr when used with drugs metabolized by the liver. Zonisamide has been associated with development of renal calculi. It is supplied as Zonegran in 100?mg tablets.

ACTH.

This is the preferred drug for the management of infantile spasms, although the dose and duration of therapy are not uniform. Prednisone is equally effective. A common schedule includes ACTH, 20 U/day IM for 2 wk, and if no response occurs, the dosage is increased to 30 and then 40 U/day IM for an additional 4 wk. Unless seizure control is complete, ACTH is replaced with oral prednisone, 2?mg/kg/24?hr

for 2 wk. If the seizures persist, prednisone is given for an additional 4 wk. The side effects of ACTH include hyperglycemia, hypertension, electrolyte abnormalities, gastrointestinal disturbances, infection, and transient brain shrinkage observed by CT scanning. ACTH and prednisone are equally effective for the treatment of cryptogenic and symptomatic seizures, and control can be expected in approximately 70% of patients. There is no relationship between the ease or degree of seizure control and ultimate neurologic and cognitive outcome. The response to medication is usually apparent within a few weeks of therapy, but one third of patients who respond suffer relapse when the ACTH or prednisone is discontinued.

Ketogenic Diet.

This treatment should be considered for the management of recalcitrant seizures, particularly for children with complex myoclonic epilepsy with associated tonic-clonic convulsions. The diet is also the primary therapy for infants with pyruvate dehydrogenase deficiency and glucose transporter protein deficiency and appears safe and effective for infants with epilepsy who are younger than 2 yr of age. The diet restricts the quantity of carbohydrate and protein, and most calories are provided as fat. Some children older than 2–3 yr will not tolerate this fatty, unpalatable diet. Because the diet demands precise weighing of foodstuffs and is time consuming to prepare, it is not accepted by all families. Some children respond to a liberalized ketogenic diet that substitutes medium-chain triglycerides for the high-fat content of the former diet. Although the mechanism of action of the ketogenic diet is unknown, some evidence shows that it exerts an anticonvulsant effect secondary to elevated levels of ß-hydroxybutyrate and acetoacetate resulting from the ketosis. The use of valproic acid is contraindicated in association with the ketogenic diet, because the risk of hepatotoxicity is enhanced.

Surgery for Epilepsy.

Surgery should be considered for children with intractable seizures unresponsive to anticonvulsants. Certain children, particularly those with focal seizures, are candidates for surgery. Although the history and neurologic examination may suggest a focal onset of seizure activity, an EEG is critical in documenting the localization and extent of the epileptogenic discharges. Prolonged EEG recording with video monitoring, which may be frequently necessary, is essential for precise localization of the epileptogenic area. It is often helpful to decrease or discontinue the anticonvulsant in hospitalized patients to increase the probability of recording ictal and interictal epileptogenic activity. When the EEG used with sphenoidal electrodes

does not adequately localize the focus, placement of subdural electrodes may provide invaluable information. Subdural electrodes are particularly useful in the investigation of epileptogenic foci in sites other than the temporal lobe. EEG studies are complemented by neuropsychologic testing, the Wada (intracarotid injection of amobarbital to establish the dominant hemisphere) test, single-photon-emission CT (SPECT) or PET scanning, and neuroimaging procedures, including CT scanning, MRI, and functional MRI (fMRI). Some centers use magnetic source imaging/magnetoelectroencephalograms (MSI/MEG), which localize seizure discharges more precisely than other techniques. The results of surgery in children with a well-defined focus of epileptogenic activity supported by an identical structural lesion on CT scanning or MRI scan are extremely favorable and are comparable to those in adults with similar pathology.

Vagal Nerve Stimulation.

Animal experiments have suggested that electrical stimulation of the left vagal nerve will interrupt or prevent seizures. In a double-blind trial in 60 children, 16 of whom were younger than 12 yr of age, left vagal nerve stimulation produced by an implanted device reduced seizures by 31–42% over 18 mo, suggesting that it may be a safe adjunctive therapy for patients refractory to other therapies.

Counseling the Parents.

Most parents are initially frightened by the diagnosis of epilepsy and require support and accurate information. Physicians should anticipate questions, including inquiries about the duration of the seizure disorder, side effects of medication and convulsions, etiology, social and academic repercussions, and parental guilt. Parents usually wish to know if restrictions should be placed on the child and whether the teacher should be informed. Others inquire about the genetic implications, including the risks for future children. Parents should be encouraged to treat their child as normally as possible. For most children with epilepsy, restriction of physical activity is unnecessary except that they must be attended by a responsible adult while bathing and swimming. The mechanism of the seizure and what epilepsy means should be explained, and the purpose and side effects of the specific anticonvulsant should be reviewed. Parents who understand the fundamental action and purpose of anticonvulsants and the need for a specific drug regimen are generally compliant. Counseling should include first-aid measures to be used if the seizure recurs. Fortunately, most parents and children readily adapt to the seizure disorder and to the requirement for long-term anticonvulsants. Most cases of epilepsy in children are well controlled with medication; the children have normal intelligence and can be expected to lead normal lives. These children require careful monitoring of their academic performance because learning disabilities are more common in children with epilepsy than in the general population. Cooperation and understanding among the parents, physician, teacher, and child enhance the outlook for patients with epilepsy.

586.7 Neonatal Seizures (see Chapters 86–89)

Neonates are at particular risk for the development of seizures because metabolic, toxic, structural, and infectious diseases are more likely to be manifested during this time than at any other period of life. Neonatal seizures are dissimilar from those in a child or adult because generalized tonic-clonic convulsions tend not to occur during the 1st mo of life. The arborization of axons and dendritic processes as well as myelination is incomplete in the neonatal brain. A seizure discharge, therefore, cannot readily be propagated throughout the neonatal brain to produce a generalized seizure. At least five seizure types are recognizable in newborn infants.

Clinical Manifestations and Classification.

Focal seizures consist of rhythmic twitching of muscle groups, particularly those of the extremities and face. These seizures are often associated with localized structural lesions as well as with infections and subarachnoid hemorrhage. *Multifocal clonic* convulsions are similar to focal clonic seizures but differ in that many muscle groups are involved, frequently several simultaneously. *Tonic seizures* are characterized by rigid posturing of the extremities and trunk and are sometimes associated with fixed deviation of the eyes. *Myoclonic seizures* are brief focal or generalized jerks of the extremities or body that tend to involve distal muscle groups. *Subtle seizures* consist of chewing motions, excessive salivation, and alterations in the respiratory rate including apnea, blinking, nystagmus, bicycling or pedaling movements, and changes in color.

Neonatal seizures may be difficult to recognize clinically, and some neonatal behaviors that were considered previously to be convulsions are not substantiated by the EEG recording. Nonetheless, several clinical features distinguish seizures from nonepileptic activity in neonates. Autonomic changes such as tachycardia and elevation of the blood pressure are common with seizures but do not occur with nonepileptic events. Nonepileptic movements are suppressed by gentle restraint, but true seizures are not. Nonepileptic phenomena are enhanced by sensory stimuli that have no influence on seizures. Correct classification of neonatal seizures is important for appropriate selection of anticonvulsant therapy. Studies using polygraphic EEG recording with video monitoring have greatly enhanced the characterization of neonatal seizures and their medical management.

EEG Classification of Neonatal Seizures

CLINICAL SEIZURE WITH A CONSISTENT EEG EVENT.

In this category, a clinical seizure occurs in relationship to seizure activity recorded on the EEG and includes focal clonic, focal tonic, and some myoclonic seizures. These seizures are clearly epileptic and are likely to respond to an anticonvulsant.

CLINICAL SEIZURES WITH INCONSISTENT EEG EVENTS.

Neonates may have a clinical seizure without a corresponding seizure discharge. This is observed with all generalized tonic seizures and subtle seizures and with some myoclonic seizures. These infants tend to be neurologically depressed or comatose as a result of hypoxic-ischemic encephalopathy. Seizures in this category are likely to be of nonepileptic origin and may not require or respond to antiepileptics.

ELECTRICAL SEIZURES WITH ABSENT CLINICAL SEIZURES.

Electrical seizures associated with a markedly abnormal background EEG may develop in comatose infants who are not on anticonvulsants. Conversely, electrical seizures may persist in patients with focal tonic or clonic seizures without clinical signs after the introduction of an anticonvulsant.

Etiologic Diagnosis.

The most common cause of neonatal seizures, hypoxic-ischemic encephalopathy, is discussed in Chapter 88.7 . Many additional disorders are likely to cause seizures, including metabolic, infectious, traumatic, structural, hemorrhagic, embolic, and maternal disturbances. Because seizures in neonates may indicate a serious, life-threatening, and potentially reversible disease, it is imperative that a timely and organized approach to the investigation of neonatal seizures be carried out.

Careful neurologic examination of the infant may uncover the cause of the seizure disorder. Examination of the retina may show the presence of chorioretinitis, suggesting a congenital infection in which case TORCH titers of mother and infant are indicated. The **Aicardi syndrome,** which occurs exclusively in infant girls, is associated with coloboma of the iris and retinal lacunae, refractory seizures, and absence of the corpus callosum. Inspection of the skin may show hypopigmented lesions characteristic of tuberous sclerosis or the typical crusted vesicular lesions of incontinentia pigmenti; both neurocutaneous syndromes are associated with generalized myoclonic seizures beginning early in life. An unusual body odor suggests an inborn error of metabolism.

Blood should be obtained for determinations of glucose, calcium, magnesium, electrolytes, and blood urea nitrogen. If hypoglycemia is a possibility, a serum Dextrostix testing is indicated so that treatment can be initiated immediately. See Chapter 96.2 for a discussion of the diagnosis and treatment of hypoglycemia. Hypocalcemia may occur in isolation or in association with hypomagnesemia. A lowered serum calcium level is often associated with birth trauma or a CNS insult in the perinatal period. Additional causes include maternal diabetes, prematurity, DiGeorge syndrome, and high-phosphate feedings. See Chapters 48.9 and 95 for a full discussion. Hypomagnesemia (<1.5?mg/dL) is often associated with

hypocalcemia and occurs particularly in infants of malnourished mothers. In this situation, the seizures are resistant to calcium therapy but respond to intramuscular magnesium, 0.2?mL/kg of a 50% solution of $MgSO_4$. See Chapter 95 for diagnosis and treatment of hypomagnesemia. Serum electrolyte measurement may indicate significant hyponatremia (serum sodium <135?mEq/L) or hypernatremia (serum sodium >150?mEq/L) as a cause of the seizure disorder.

A *lumbar puncture* is indicated in virtually all neonates with seizures, unless the cause is obviously related to a metabolic disorder such as hypoglycemia or hypocalcemia secondary to feeding of high concentrations of phosphate. These latter infants are normally alert interictally and usually respond promptly to appropriate therapy. The CSF findings may indicate a bacterial meningitis or aseptic encephalitis (see Chapters 98 and 594). Prompt diagnosis and appropriate therapy improve the outcome for these infants. Bloody CSF indicates a traumatic tap or a subarachnoid/intraventricular bleed. Immediate centrifugation of the specimen may assist in differentiation of the two disorders. A clear supernatant suggests a traumatic tap, and a xanthochromic color suggests a subarachnoid bleed. However, mildly jaundiced normal infants may have a yellowish discoloration of the CSF that makes inspection of the supernatant less reliable in the newborn period.

Many *inborn errors of metabolism* cause generalized convulsions in the newborn period. Because these conditions are often inherited in an autosomal recessive or X-linked recessive fashion, it is imperative that a careful family history be obtained to determine whether siblings or close relatives developed seizures or died at an early age. Serum ammonia determination is useful for screening for suspected urea cycle abnormalities, such as ornithine transcarbamylase, arginosuccinic lysate, and carbamoylphosphate synthetase deficiencies. In addition to having generalized clonic seizures, these infants present during the first few days of life with increasing lethargy progressing to coma, anorexia and vomiting, and a bulging fontanel. If the blood gases show an anion gap and a metabolic acidosis with hyperammonemia, urine organic acids should be immediately determined to investigate the possibility of methylmalonic or propionic acidemia. Maple syrup urine disease (MSUD) should be suspected when a metabolic acidosis occurs in association with generalized clonic seizures, vomiting, and muscle rigidity during the 1st wk of life. The result of a rapid screening test using 2,4-dinitrophenylhydrazine that identifies ketoderivatives in the urine is positive in MSUD. Additional metabolic causes of neonatal seizures include nonketotic hyperglycemia, a lethal condition characterized by markedly elevated plasma and CSF glycine levels, persistent generalized seizures, and lethargy rapidly leading to coma; ketotic hyperglycinemia in which seizures are associated with vomiting, fluid and electrolyte disturbances, and a metabolic acidosis; and Leigh disease suggested by elevated levels of serum and CSF lactate or an increased lactate/pyruvate ratio. Biotinidase deficiency should also be considered. A comprehensive description of the diagnosis and management of these metabolic diseases is discussed in Part X.

Unintentional *injection of a local anesthetic* into a fetus during labor can produce intense tonic seizures. These infants are often thought to have had a traumatic delivery because they are flaccid at birth, they have abnormal brainstem reflexes, and they show signs of respiratory depression that sometimes requires ventilation. Examination may show a needle puncture of the skin or a perforation or laceration of the scalp. An elevated serum anesthetic level confirms the diagnosis. The treatment consists of supportive measures and promotion of urine output by administering intravenous fluids with appropriate monitoring to prevent fluid overload.

Benign familial neonatal seizures, an autosomal dominant condition, begins on the 2nd–3rd day of life, with a seizure frequency of 10–20/day. Patients are normal between seizures, which stop in 1–6 mo. *Fifth-day fits* occur on day 5 of life (4–6 days) in normal-appearing neonates. The seizures are multifocal and are present for less than 24?hr. The prognosis is good.

Pyridoxine dependency, a rare disorder, must be considered when generalized clonic seizures begin shortly after birth with signs of fetal distress in utero. These seizures are particularly resistant to conventional anticonvulsants, such as phenobarbital or phenytoin. The history may suggest that similar seizures occurred in utero. Some cases of pyridoxine dependency are reported to begin later in infancy or in early childhood. This condition is inherited as an autosomal recessive. Although the precise biochemical defect is unknown, pyridoxine is essential for the synthesis of glutamic acid decarboxylase, which, in turn, is required for the synthesis of GABA. In affected infants, large amounts of pyridoxine are required to maintain adequate production of GABA. When pyridoxine-dependent seizures are suspected, pyridoxine, 100–200?mg IV, should be administered intravenously during the EEG, which should be promptly completed once the diagnosis is considered. The seizures abruptly cease, and the EEG normalizes during the next few hours.

However, not all cases of pyridoxine dependency respond dramatically to the initial bolus of IV pyridoxine. Therefore, A 6-wk trial of oral pyridoxine (10–20?mg/day) is recommended for infants in whom a high index of suspicion continues after a negative response to IV pyridoxine. In the future, measurement of CSF and plasma pyridoxal-5-phosphate may prove to be the more precise method of confirming the diagnosis of pyridoxine dependency. These children require lifelong supplementation of oral pyridoxine, 10?mg/day. Generally, the earlier the diagnosis and therapy with pyridoxine, the more favorable is the outcome. Untreated children have persistent seizures and are uniformly severely mentally retarded (see also Chapter 44.6).

Drug withdrawal seizures can present in the newborn nursery but may take several weeks to develop because of prolonged excretion of the drug by the neonate. The incriminated drugs include barbiturates, benzodiazepines, heroin, and methadone. The infant may be jittery, irritable, and lethargic and may show myoclonus or frank clonic seizures. The mother may deny the use of drugs; a serum or urine analysis may identify the responsible agent (see Chapter 95).

Infants with focal seizures, suspected stroke or intracranial hemorrhage, and severe *cytoarchitectural abnormalities* of the brain—including lissencephaly and schizencephaly—who clinically may appear normal or microcephalic should undergo MRI or CT scan. Indeed, many recommend imaging of all neonates with seizures unexplained by serum glucose, calcium, or electrolyte disorders. Infants with chromosome abnormalities and adrenoleukodystrophy are also at risk for seizures and should be evaluated with investigation of a karyotype and serum long-chain fatty acids, respectively.

Treatment.

Anticonvulsants should be used in the treatment of infants with seizures secondary to hypoxic-ischemic encephalopathy or an acute intracranial bleed (see Chapters 88.2 and 88.7). The dose and administration of phenobarbital, diazepam, and other medications for the treatment of neonatal seizures are discussed in Chapter 88.7 . Phenytoin and phenobarbital are equally but incompletely effective as anticonvulsants in neonates, controlling seizures in less than half of cases. The greater use of EEG recording in infants with subtle seizures has identified a number of patients with abnormal movements unrelated to seizure discharges.

Prognosis.

This depends mainly on the primary cause of the disorder or the severity of the insult. In the case of hypoglycemic infants of a diabetic mother or hypocalcemia associated with excessive phosphate feedings, the prognosis is excellent. Conversely, a child with intractable seizures due to severe hypoxic-ischemic encephalopathy or a cytoarchitectural abnormality of the brain usually does not respond to anticonvulsants and is susceptible to status epilepticus and early death. The challenge for the physician is to identify patients who will recover with prompt treatment and to avoid delays in diagnosis that could lead to severe, irreversible neurologic damage.

586.8 Status Epilepticus

Status epilepticus is defined as a continuous convulsion lasting longer than 30?min or the occurrence of serial convulsions between which there is no return of consciousness. Status epilepticus may be classified as generalized (tonic-clonic, absence) or partial (simple, complex, or with secondary generalization). Generalized tonic-clonic seizures predominate in cases of status epilepticus. Status epilepticus is a medical emergency that requires an organized and skillful approach to minimize the associated mortality and morbidity.

Etiology.

There are three major subtypes of status epilepticus in children: prolonged *febrile seizures; idiopathic status epilepticus,* in which a seizure develops in the absence of an underlying CNS lesion or insult; and *symptomatic status epilepticus*, when the seizure occurs as a result of an underlying neurologic disorder or a metabolic abnormality. A febrile seizure lasting for more than 30?min, particularly in a child younger than 3 yr of age, is the most common cause of status epilepticus. The idiopathic group includes epileptic patients who have had sudden withdrawal of anticonvulsants (especially benzodiazepines and barbiturates) followed by status epilepticus. Epileptic children who are given anticonvulsants on an irregular basis or who are noncompliant are more likely to develop status epilepticus. Status epilepticus may also be the initial presentation of epilepsy. Sleep deprivation and an intercurrent infection tend to render epileptic patients more susceptible to status epilepticus. The mortality and morbidity among patients with prolonged febrile seizures and idiopathic status epilepticus are low.

Status epilepticus owing to other causes has a much higher mortality rate, and the cause of death usually is directly attributable to the underlying abnormality. Unlike those with idiopathic status epilepticus, many of these children have not previously had a convulsion. Severe anoxic encephalopathy presents with seizures during the first few days of life, and the ultimate prognosis relates partly to the ease in controlling the seizures. A prolonged convulsion may be the initial manifestation of encephalitis, and epilepsy may be a long-term complication of meningitis. Infants with congenital malformations of the brain (e.g., lissencephaly or schizencephaly) may have recurrent episodes of status epilepticus that are frequently refractory to anticonvulsants. Inborn errors of metabolism may present with status epilepticus in newborns. Affected infants often have a progressive loss of consciousness associated with failure to thrive and excessive vomiting. Electrolyte abnormalities, hypocalcemia, hypoglycemia, drug intoxication, Reye syndrome, lead intoxication, extreme hyperpyrexia, and brain tumors, particularly in the frontal lobe, are additional causes of status epilepticus.

Pathophysiology.

The relationship between the neurologic outcome and the duration of status epilepticus is unknown in children and adults. Some evidence shows that the period of status epilepticus that produces neuronal injury in a child is less than that for an adult. In primates, pathologic changes can occur in the brain of ventilated animals after 60?min of constant seizure activity when metabolic homeostasis is maintained. Cell death may result from excessive release of the excitatory neurotransmitter glutamate and excessive stimulation of glutamate receptors, a process known as “excitotoxicity.” The most vulnerable areas of the brain include the hippocampus, amygdala,

---

cerebellum, middle cortical area, and thalamus. Characteristic acute pathologic changes consist of venous congestion, small petechial hemorrhages, and edema. Ischemic cellular changes are the earliest histologic finding, followed by neuronophagia, microglial proliferation, cell loss, and increased numbers of reactive astrocytes. Neuronal concentrations of calcium, arachidonic acid, and prostaglandins increase and may promote cell death. Prolonged generalized seizure activity may lead to dysfunction of the autonomic nervous system with hypotension and shock as well as to lactic acidosis, myoglobinuria, elevated lactic acid levels, and acute tubular necrosis.

Several investigations have shown that seizures become more difficult to stop and the chances of neuronal injury increase when seizures persist beyond a *transitional period* that varies between 20 and 60?min in animals during constant seizure activity. Treatment of children should be directed to supporting vital functions and to controlling the convulsions as expeditiously as possible, because the precise transitional period in humans is unknown.

Treatment.

Initial treatment of patients begins with an assessment of the respiratory and cardiovascular systems. Children should be transferred to an intensive care unit if possible. The oral airway is secured and inspected for patency, and the pulse, temperature, respirations, and blood pressure are recorded. Excessive oral secretions are removed by gentle suction, and a properly fitting face mask attached to oxygen is applied. If patients do not respond to oxygen by mask or are difficult to ventilate by an Ambu bag, consideration should be given to intubation and assisted ventilation. A nasogastric tube is placed in position, and an IV catheter is immediately inserted. If hypoglycemia is confirmed by Dextrostix, a rapid infusion of 5?mL/kg of 10% dextrose is provided. Blood is obtained for a CBC and for determination of electrolytes (including calcium, phosphorus, and magnesium), glucose, creatinine, lactate, and anticonvulsant levels, if indicated. Blood and urine may be obtained for metabolic studies and toxicology, keeping in mind that some drugs potentiate or precipitate status epilepticus (e.g., amphetamines, cocaine, phenothiazines, theophylline in toxic levels, and tricyclic antidepressants). Arterial

blood gases should be determined, and it is wise to monitor oxygen saturation (SaO_2) with an oximeter. Examination of the CSF is imperative if meningitis or encephalitis is considered, unless there is a contraindication to the procedure. In this case, appropriate antibiotics should be administered, followed by imaging studies, before a lumbar puncture is attempted. If the seizures are refractory to the front-line anticonvulsants or if the patient is paralyzed and is on a respirator, continuous EEG monitoring is important to assess the frequency of seizure discharges, their location, and the response to anticonvulsant therapy.

A physical and neurologic examination should be carried out concurrently to assess the following: evidence of trauma; papilledema, a bulging anterior fontanel, or lateralizing neurologic signs suggesting increased ICP; manifestations of sepsis or meningitis; retinal hemorrhages that may indicate a subdural hematoma; Kussmaul breathing and dehydration suggestive of metabolic acidosis or irregular respirations signifying brainstem dysfunction; evidence of failure to thrive, a peculiar body odor, or abnormal hair pigmentation that suggests an inborn error of metabolism; and constriction or dilatation of pupils suggesting a toxin or drugs as the cause of the status epilepticus. A comprehensive examination should be undertaken once the seizures are under control. Further investigation of the patient including neuroradiologic studies depends on the physical and neurologic findings and on a precise history of the seizure type and frequency.

Drugs should always be administered IV in the management of status epilepticus; the IM route is unreliable because some drugs are sequestered by muscle. One of the major problems in the management of status epilepticus is the inappropriate use of anticonvulsants. An unsuitably low drug dose is too often given, and with lack of response, another antiepileptic is introduced immediately. Care should be given with regard to how the anticonvulsant is administered. Phenytoin forms a precipitate in glucose solutions and is rendered ineffective. Other drugs interact with plastic containers or are altered by sunlight (e.g., paraldehyde). It is essential to have resuscitation equipment at the bedside and the ability to intubate and ventilate the patient immediately if respiratory depression occurs.

A *benzodiazepine* (diazepam, lorazepam, or midazolam) may be used initially, because these are effective for immediate control of prolonged tonic-clonic seizures in most children. Diazepam should be given IV directly into the vein (not the tubing) in a dose of 0.1–0.3?mg/kg at a rate no greater than 2?mg/min for a maximum of three doses. Respiratory depression and hypotension can occur, especially if administered with a barbiturate. Benzodiazepines may be as effective as pentobarbital with fewer side effects. Diazepam is effective in the management of tonic-clonic status, but the drug has a short half-life and seizures thus recur unless a longer acting anticonvulsant is administered simultaneously. Lorazepam is an equally effective short-term anticonvulsant, with a greater duration of action and decreased likelihood of producing hypotension and respiratory arrest. The recommended dose is 0.05–0.1?mg/kg IV administered slowly. The dose of midazolam is 0.15–0.3?mg/kg IV. If an IV line cannot be established or the child is some distance from a medical center, rectal diazepam or lorazepam can be used safely. Diazepam diluted in 3?mL 0.9% NaCl is placed into the rectum by a syringe and a flexible tube at a dose of 0.3–0.5?mg/kg. The effective dose of rectal lorazepam is 0.05–0.1?mg/kg. Therapeutic serum levels occur within 5–10?min. Sublingual lorazepam may be used to treat children with serial seizures that tend to develop into status epilepticus while the children are at home. The dose of sublingual lorazepam is 0.05–0.1?mg/kg. The tablet is placed under the patient's tongue and dissolves in a few seconds. Rectal diazepam gel (Diastat, pediatric doses of 2.5, 5, or 10?mg) may also be useful.

After administration of diazepam or lorazepam, several options are available for further management. If the convulsive activity ceases after diazepam or lorazepam therapy or if the seizures persist, *phenytoin* is given immediately. The loading dose of phenytoin is 15 up to 30?mg/kg IV (given in 10?mg/kg increments) at the rate of 1?mg/kg/min. The phenytoin prodrug fosphenytoin has advantages over the older formulation because it is water soluble, less irritating after IV injection, and well absorbed after intramuscular injection. Parenteral fosphenytoin (Cerebyx) is formulated in phenytoin equivalent (PE) units to allow the administration of the same amount of phenytoin despite its higher molecular weight (150?mg of fosphenytoin equals 100?mg of phenytoin). The dosage in PE units is the same as for the older phenytoin preparation. The older preparation of phenytoin may be safely added to half-normal or normal saline but not to glucose solutions; the undiluted drug can cause pain, irritation, and phlebitis of the vein. Electrocardiography is recommended during the loading phase to identify arrhythmias and bradycardia, a rare complication in children. Systemic hypotension may also complicate IV phenytoin. If the seizures do not recur, a maintenance dose of 3–9?mg/kg divided into two equal doses daily is begun 12–24?hr later. Serum phenytoin levels should be monitored because the maintenance dose varies considerably with age. Phenytoin is not always effective in controlling tonic-clonic status epilepticus, in which case an alternative drug is necessary. In some centers, *phenobarbital* is initiated before phenytoin. It is given in a loading dose of 15–20?mg/kg or in neonates 20–30?mg/kg IV during 10–30?min. With control of the seizures, the maintenance dose is 3–5?mg/kg/24?hr divided into two equal doses.

If the status epilepticus is not controlled by the preceding strategy, the physician must make some important therapeutic

decisions, because it is likely the *transitional period* has passed. The choices for further drug management include paraldehyde, a diazepam infusion, barbiturate coma, or general anesthesia. By this stage, the patient is usually sedated and may show signs of respiratory depression, necessitating elective intubation and assisted ventilation.

Constant IV infusion of either midazolam (0.20?mg/kg bolus, 20–400?µg/kg/hr infusion) or propofol (1–2?mg/kg, 2–10?mg/kg/hr infusion) has been effective in managing seizures during status epilepticus unresponsive to other anticonvulsants. If seizures continue, serious consideration is given to induction of barbiturate coma. In an intensive care unit, the patient is placed on a ventilator and a continuous EEG monitor. The initial IV loading dose of thiopental is 2–4?mg/kg and is then titrated to achieve a burst suppression EEG pattern. Barbiturate coma is continued for at least 48?hr, followed by cessation of thiopental until the serum phenobarbital level falls to the therapeutic range. Barbiturate coma requires careful monitoring because hypotension due to myocardial depression often requires pressor therapy.

Paraldehyde is relatively safe for administration to children. A 5% solution of paraldehyde is prepared by adding 1.75?mL of paraldehyde (1?g/mL) to D5W to a total volume of 35?mL. The loading dose is 150–200?mg/kg IV slowly for 15–20?min, and then seizure control is maintained with an infusion of 20?mg/kg/hr in a 5% concentration in a glass bottle, because the drug is incompatible with plastic. The IV drip rate may be lowered as the seizures and EEG improve. The drug should be freshly opened, because outdated paraldehyde can deteriorate to acetylaldehyde and acetic acid.

General anesthesia is an alternative adjunct to the management of status epilepticus if conventional drug therapy is not effective or if barbiturate coma is not an option. Several agents have been used successfully, including halothane and isoflurane. General anesthesia probably acts by reversing cerebral anoxia and the concomitant metabolic abnormalities, allowing the previously administered anticonvulsants to exert their effect. The major disadvantage of general anesthesia is that it must be administered by well-trained personnel with anesthetic gas scavenging equipment for prolonged periods.

Valproic acid has been an effective anticonvulsant in the management of several types of seizures. Valproic acid is available as an injectable and may be given IV. Preliminary studies recommend a loading dose of IV valproic acid, 10–15?mg/kg. IV valproic acid may become a useful drug for status epilepticus.

The use of anticonvulsant therapy after status epilepticus is controversial. There is little question that a long-term antiepileptic should be maintained in children with a progressive neurologic disorder or with a history of recurrent seizures before the onset of status epilepticus. However, it is unlikely that a lengthy period of anticonvulsant treatment is necessary after an initial attack of idiopathic status epilepticus, particularly when a prolonged febrile seizure was the cause. Anticonvulsant therapy is maintained arbitrarily for 3 mo in this case and is discontinued if the child remains asymptomatic.

Prognosis.

Status epilepticus produces potentially life-threatening disturbances in physiologic function and the mortality rate of status epilepticus is approximately 5%. The greatest number of deaths occur in the symptomatic group, most of whom have a serious and life-threatening CNS disorder known before the onset of status epilepticus. In the absence of a progressive neurologic insult (e.g., herpes encephalitis) or metabolic disorder, the morbidity from status epilepticus is low. The fact that long-term sequelae such as hemiplegia, extrapyramidal syndromes, mental retardation, and epilepsy are more common in children younger than 1 yr following status epilepticus is related to the fact that this group is more likely to have a premorbid underlying CNS disorder than are older children. Nevertheless, there remains considerable debate over whether prolonged status epilepticus can damage the brain as has been shown in animal experiments. It is noteworthy that febrile status epilepticus in a neurologically impaired child is a risk factor for subsequent febrile as well as nonfebrile seizures, but febrile status in an otherwise normal child does not increase the risk of seizures. MRI brain scan performed in several infants demonstrated that complex febrile convulsions can occasionally be associated with acute hippocampal injury progressing to atrophy. In some of these infants, pathology and brain imaging also demonstrated evidence of pre-existing cerebral dysgenesis. These cases suggest that hippocampal sclerosis associated with status epilepticus may reflect interaction between pre-existing and acquired processes.

Chapter 587 - Conditions that Mimic Seizures

Michael V. Johnston

Several conditions share common features with epilepsy. Because these disorders may be associated with altered levels of consciousness, tonic or clonic movements, or cyanosis, they are often confused with epilepsy. Affected children may be inappropriately placed on many anticonvulsants with no response and some risk; conditions that mimic epilepsy are refractory to antiepileptic drugs. The treatment of these children differs significantly from those with epilepsy.

Benign Paroxysmal Vertigo.

Benign paroxysmal vertigo (BPV) typically develops in toddlers and is relatively rare beyond 3 yr of age. The attacks develop suddenly and are associated with ataxia, causing the child to fall or refuse to walk or sit. Horizontal nystagmus may be evident during the duration of the attack. The child appears frightened and pale. Nausea and vomiting may be prominent. Consciousness and the ability to verbalize are not disturbed; lethargy or drowsiness do not follow completion of the episode. The attacks vary in duration (seconds to minutes), frequency (daily to monthly), and intensity. A rotational sensation (vertigo) is verbalized by older children with BPV. These children are susceptible to motion sickness and may develop migraine headaches several years later, suggesting a relationship between BPV and migraine. Neurologic evaluation

characteristically yields negative results, except for the finding of abnormal vestibular function detected by ice water caloric testing. Patients with clusters of attacks usually respond to diphenhydramine, 5?mg/kg/24?hr with a maximum of 300?mg/24?hr PO, IM, IV, or per rectum.

Night Terrors.

Night terrors are common, particularly in boys between 5 and 7 yr of age (see Chapter 22). They occur in 1–3% of children and are usually short-lived. A night terror has a sudden onset, usually between midnight and 2:00 am during stage 3 or 4 of slow-wave sleep. The child screams and appears frightened, with dilated pupils, tachycardia, and hyperventilation. There is little or no verbalization; the child may thrash violently, cannot be consoled, and is unaware of parents or surroundings. Sleep follows in a few minutes, and there is total amnesia the following morning. Approximately one third of children with night terrors experience somnambulism. An underlying emotional disorder should be explored in children with persistent and prolonged night terrors. A short course of diazepam or imipramine may be considered for treatment of protracted night terrors while the family dynamics are under investigation.

Breath-Holding Spells.

A breath-holding spell can be a frightening experience for parents because the infant becomes lifeless and unresponsive owing to cerebral anoxia at the height of the attack. There are two major types of breath-holding spells: the more common cyanotic form and the pallid form. Also see Chapter 25 .

CYANOTIC SPELLS.

A cyanotic breath-holding spell is usually predictable and is always provoked by upsetting or scolding an infant. The episode is heralded by a brief, shrill cry followed by forced expiration and apnea. There is rapid onset of generalized cyanosis and a loss of consciousness that may be associated with repeated generalized clonic jerks, opisthotonos, and bradycardia. Results of an interictal electroencephalogram (EEG) are normal. A breath-holding spell can occur repeatedly within a few hours or it can recur sporadically, but it is always stereotyped. Breath-holding spells are rare before 6 mo of age, they peak at about 2 yr of age, and they abate by 5 yr of age. The management of breath-holding spells concentrates on the support and reassurance of the parents. Some parents feel that whatever the physician recommends, they must splash cold water on the face, turn the child upside down, or initiate mouth-to-mouth resuscitation and even cardiopulmonary resuscitation. A thorough examination followed by an explanation of the mechanism of breath-holding spells is reassuring for most parents. The counseling session should emphasize the need for both parents to be consistent and not reinforce the child's behavior after the child recovers from the spell. This may be accomplished by placing the child safely in bed and by refusing to cuddle, play, or hold the child for a given period of time until recovery is complete.

PALLID SPELLS.

These spells are much less common than cyanotic breath-holding spells, but they share several characteristics. Pallid spells are typically initiated by a painful experience, such as falling and striking the head or a sudden startle. The child stops breathing, rapidly loses consciousness, becomes pale and hypotonic, and may have a tonic seizure. Bradycardia with periods of asystole of longer than 2?sec may be recorded. The interictal EEG is normal. Pallid spells can in some cases be induced spontaneously in the laboratory by ocular compression that produces the oculocardiac reflex, afferent stimulation of the trigeminal nerve, and efferent inhibition of the heart by way of the vagus nerve. This procedure should not be attempted by an inexperienced physician, and appropriate resuscitation equipment should be readily available. Most children respond to conservative measures as outlined for

cyanotic spells, but a trial of an anticholinergic, oral atropine sulfate 0.01?mg/kg/24?hr in divided doses with a maximum daily dose of 0.4?mg, which increases the heart rate by blocking the vagus nerve, may be considered in refractory cases. Atropine should not be prescribed during very hot weather because an episode of hyperpyrexia may be initiated.

Syncope

SIMPLE SYNCOPE.

Syncope follows an alteration in brain metabolism, the consequence of decreased cerebral blood flow, usually secondary to systemic hypotension. Decreased blood flow causes loss of consciousness, and the concomitant ischemia influences the higher cortical centers to release their inhibiting influence on the reticular formation within the brainstem. Neuronal discharges from the reticular formation then produce brief tonic contractions of the muscles of the face, trunk, and extremities in approximately 50% of patients with syncope. During a syncopal episode, a child may have fixed upward deviation of the eyes that can be confused with epilepsy. Simple syncope results from vasovagal stimulation and is precipitated by pain, fear, excitement, and extended periods of standing still, particularly in a warm environment. The EEG shows transient slowing during the attack but no seizure discharges. Simple syncope is uncommon before age 10–12 yr but is quite prevalent in adolescent girls. Tilt-table testing is an effective method of producing symptoms, including hypotension, in the majority of children with unexplained syncope. Most patients with positive tilt-table test results have vasovagal syncope, which if recurrent responds favorably to oral ß-adrenergic blocking agents. Syncope can usually be differentiated from a seizure because of its short duration, associated symptoms of nausea and perspiration, and complete orientation after the event.

COUGH SYNCOPE.

This is most common in asthmatic children. It often occurs shortly after the onset of sleep, and the coughing paroxysm abruptly awakens the child. The patient's face becomes plethoric, and the child perspires, becomes agitated, and is frightened. Loss of consciousness is associated with generalized muscle flaccidity, vertical upward gaze, and clonic muscle contractions lasting for several seconds. Urinary incontinence is frequent. Recovery begins within seconds, and consciousness is usually restored a few minutes later. The child has no recollection of the attack except for the events surrounding the paroxysm of coughing. Coughing produces a marked increase in intrapleural pressure followed by a lowered venous return to the right side of the heart and an associated decrease in right ventricular output. Reduction of left ventricular filling follows, and a rapidly diminished cardiac output results in altered cerebral blood flow, cerebral hypoxia, and a loss of consciousness. The cornerstone of management for asthmatic children with cough syncope is an aggressive approach to the prevention of bronchoconstriction.

PROLONGED QT SYNDROME.

The incidence of the prolonged QT syndrome is 1/10,000 to 1/15,000. The prolonged QT syndrome is characterized by sudden loss of consciousness during exercise or an emotional and stressful experience (see Chapter 428.4). Loss of consciousness in association with exercise or stress is rarely due to epilepsy, and in every case a cardiac cause must be considered. The onset of the condition is typically in late childhood or adolescence, although onset in infancy may mimic sudden infant death syndrome. During the period of syncope, various cardiac arrhythmias are evident, particularly ventricular fibrillation. The child may recover within minutes or die during the event. Electrocardiography may show prolongation of the QT interval due to abnormal lengthening of the QT interval, especially during carefully monitored exercise. QT intervals corrected for heart rate of 0.46?msec or greater support the diagnosis. There are at least two varieties of the syndrome: those due to acquired heart disease (myocarditis, mitral valve prolapse, electrolyte abnormalities, drug induced) and two congenital forms. The QT syndrome may be inherited as an autosomal recessive trait (Jervell and Lange-Nielsen syndrome) that is associated with deafness or as autosomal dominant (Romano-Ward syndrome). Mutations in a cardiac potassium channel gene [KvLQT1], linked to chromosome 11p15.5, account for

---

about 50% of the long QT syndrome inherited as an autosomal dominant (type 1 or LQT1). LQT2 results from a mutation in a second potassium channel gene (HERG), which is linked to chromosome 7q35-36. Type 3 long QT syndrome is the result of a mutation to a cardiac sodium channel gene (SCN5A) linked to chromosome 3p21-24, and a fourth type of long QT syndrome has been linked to chromosome 4q25-27. The gene for type 4 LQT has not been determined. All family members of an affected patient should have a 12-lead electrocardiogram. Further testing may include carefully supervised exercise tests or Holter monitoring. ß-Adrenergic-antagonist drugs are usually effective and may be lifesaving. Permanent implantable cardiac pacing or left cervicothoracic sympathectomy may also be considered if drug therapy is not effective. Parents should be taught cardiopulmonary resuscitation, because exercise restriction and drug therapy may be ineffective for some children.

Paroxysmal Kinesigenic Choreoathetosis.

This disorder is characterized by a sudden onset of unilateral or occasionally bilateral choreoathetosis or dystonic posturing of a leg or an arm and associated facial grimacing and dysarthria. The condition is precipitated by sudden movement, particularly on arising from a sitting position, or by excitement and stress. The attacks rarely persist for longer than a minute and are never associated with loss of consciousness. The age of onset is typically between 8 and 14 yr, but the condition may begin as early as 2 yr. The child may have several attacks daily, or they may be intermittent, occurring once or twice a month. Results of neurologic examination, EEG, and neuroimaging studies are normal, and neuropathologic studies in a few cases showed no abnormalities. Most reported cases are familial, suggestive of autosomal recessive inheritance. The attacks can be prevented by the use of anticonvulsants, particularly phenytoin. The attacks of paroxysmal kinesigenic choreoathetosis tend to diminish in frequency during adulthood, and the anticonvulsant can be successfully weaned at that time.

Shuddering Attacks.

Shuddering attacks have their onset at 4–6 mo of age and may persist to 6–7 yr of age. They produce an interesting posture, with sudden flexion of the head and trunk and shuddering or shivering movements similar to what must occur if ice-cold water is poured down the back of an unsuspecting individual. These children may have 100 attacks/day followed by several symptom-free weeks. Shuddering attacks may be the childhood precursor of benign essential tremor, because examination of parents and relatives reveals a high incidence of that common condition.

Benign Paroxysmal Torticollis of Infancy.

Infants with benign paroxysmal torticollis have recurrent attacks of head tilt associated with pallor, agitation, and vomiting with an onset between 2 and 8 mo of age. During the attack, the child resists passive head movement. There is no loss of consciousness, and spontaneous remission occurs by 2–3 yr of age. As with benign paroxysmal vertigo, abnormalities in vestibular function have been documented in these patients. Children with persistent torticollis should be investigated for abnormalities of the cervical vertebrae including dislocation or fracture, or a tumor located in the posterior fossa. Some infants with benign paroxysmal torticollis develop migraine headaches later in childhood.

Hereditary Chin Trembling.

Hereditary chin trembling may be confused with epilepsy due to repeated episodes of rapid 3/sec chin trembling movements. These brief attacks are precipitated by stress, anger, and frustration and are inherited as an autosomal dominant trait. Findings on the neurologic examination and EEG are normal.

Narcolepsy and Cataplexy.

See also Chapters 20.5 and 369 . Narcolepsy is a disorder that rarely begins before adolescence and is characterized by paroxysmal attacks of irrepressible daytime sleep, which is sometimes associated with transient loss of muscle tone (cataplexy). The incidence of narcolepsy is 1/2,000. An EEG shows that the recurrent sleep attacks consist of rapid eye movement (REM) sleep. Patients with narcolepsy are easily aroused and become spontaneously alert, whereas a convulsion is followed by a deep sleep, postictal drowsiness, lethargy, and often a headache. Modafinil acetamide, 200?mg/day PO, is superior to the stimulant drugs in the management of narcolepsy and has fewer adverse side effects. Cataplexy is also occasionally confused with epilepsy. Patients with cataplexy experience sudden loss of muscle tone and fall to the floor because of laughter, stress, or frightening experiences. Cataplectic patients do not lose consciousness but lie without moving for a few minutes until normal body tone returns. Treatment consists of scheduled naps, amphetamines, methylphenidate, tricyclic antidepressants, and counseling with respect to occupational safety and driving. The stimulant and antidepressant drugs commonly produce side effects including anxiety, euphoria, hypersomnolence, and the development of tolerance.

Rage Attacks or Episodic Dyscontrol Syndrome.

The *episodic dyscontrol syndrome*, a nonepileptic condition, can be confused with complex partial seizures. Patients develop sudden and recurrent attacks of violent physical behavior with minimal provocation. The attacks consist of kicking, scratching, biting, and shouting (including abusive and profane language). An affected child or adolescent cannot seem to control the behavior and may seem momentarily psychotic throughout the attack. The episode is followed by fatigue, amnesia, and sincere remorse. A routine EEG may show nonspecific abnormalities in patients with the rage syndrome. The EEG in such patients during the attack remains normal; this condition is thus distinguished from complex partial seizures, which always show an abnormal EEG during an attack.

Masturbation.

Masturbation or self-stimulation behavior may occur in girls between the ages of 2 mo and 3 yr. These children have repetitive stereotyped episodes of tonic posturing associated with copulatory movements, but without manual stimulation of the genitalia. The child suddenly becomes flushed and perspires, may grunt and breathe irregularly, but has no loss of consciousness. The masturbatory activity has a sudden onset, usually persists for a few minutes (rarely hours), and tends to occur during periods of stress or boredom. The examination should include a search for evidence of sexual abuse or abnormalities of the perineum, but in most cases a cause is not found. Treatment consists of reassurance that the self-stimulatory activity will subside by 3 yr of age and that no specific therapy is required.

Pseudoseizures.

The diagnosis of a pseudoseizure should be made only after a thorough history and physical examination and exclusion of “true” seizures by prolonged EEG recording when indicated. Pseudoseizures occur typically between 10 and 18 yr of age and are more frequent among girls. Pseudoseizures occur in many patients with a past history of epilepsy and in some with ongoing true seizures. A pseudoseizure may be quite realistic but frequently is bizarre, with unusual postures, verbalizations, and uncharacteristic tonic or clonic movements. There are several distinguishing features of a pseudoseizure, including lack of cyanosis, normal reaction of the pupil to light, no loss of sphincter control, normal plantar responses, and the absence of tongue biting or injury during the attack. Many patients moan or cry during a pseudoseizure, and some patients can be persuaded to have an attack on request by the physician. Patients with pseudoseizures are likely to have a neurotic personality documented by formal psychologic testing. It is not unusual to find a patient taking three or four anticonvulsants, which, of course, have no effect. The most reliable method of differentiating epilepsy from suspected pseudoseizures is to record an

attack. The EEG shows an excess of muscle artifact during the pseudoseizure but a normal background rhythm devoid of seizure discharges. After a true epileptic seizure, there is a significant increase in serum prolactin, whereas there is no change from the baseline at the termination of a pseudoseizure. **REFERENCES**

Chapter 588 - Headaches

Robert H. A. Haslam

Headache is a common problem in pediatrics. The effect of headaches on a child's academic performance, memory, personality, and interpersonal relationships, as well as school attendance, depends on their etiology, frequency, and intensity. A headache may occasionally indicate a severe underlying disorder (e.g., a brain tumor), and thus careful evaluation of children with recurrent, severe, or unconventional headaches is mandatory. Infants and children respond to a headache in an unpredictable fashion. Most toddlers cannot communicate the characteristics of a headache; rather they may become irritable and cranky, vomit, prefer a darkened room because of photophobia, or repeatedly rub their eyes and head. Children are poor historians when describing a headache and its associated symptoms. The most important causes of headache in children include migraine, increased intracranial pressure (ICP), and psychogenic factors or stress. Refractive errors, strabismus, sinusitis, and malocclusion of the teeth are much less common causes of significant headaches in children.

588.1 Migraine

Migraine is defined as a recurrent headache with symptom-free intervals and at least three of the following symptoms or associated findings: abdominal pain, nausea or vomiting, throbbing headache, unilateral location, associated aura (visual, sensory, motor), relief following sleep, and a positive family history. It is the most important and frequent type of headache in the pediatric population. School children with migraine report neck-shoulder pain, abdominal pain, back pain, and otalgia more frequently than those with nonmigrainous headache. Most migraine headaches are not severe and are readily managed by conservative measures without requiring medical attention. The youngest child reported to have developed migraine was 1 yr of age. The incidence of migraine among school-aged children between 7 and 15 yr of age was 4% in a comprehensive Swedish study. Girls are more likely to develop a migraine as adolescents, whereas boys are in the slight majority among children younger than 10 yr with migraine headaches. More than half undergo spontaneous prolonged remission after the 10th birthday. As adults, 5–10% of men and 15–20% of women have migraines. The cause of migraine headaches is unknown, but an inherited predisposition to vasomotor instability appears to be an important underlying factor. Hormonal changes, food allergies, personality traits characterized by high achievement, stress, bright flashing lights, and excessive sound all have

been implicated. Increased levels of circulating serotonin and substance P, a vasodilating polypeptide, may act directly on the extracranial and intracranial vessels.

Clinical Manifestations and Classification.

Migraine may be classified into subgroups, including common and classic migraine, migraine variants, cluster headaches, and complicated migraine. Cluster headaches rarely occur in children.

COMMON MIGRAINE (MIGRAINE WITHOUT AURA).

This migraine is not associated with an aura and is the most prevalent type of migraine in children. The headache is throbbing or pounding and tends to be unilateral at onset or throughout its duration and is located in the bifrontal or temporal regions. It may not be hemicranial in children and is less intense compared with the migraine in adults. The headache usually persists for 1–3?hr, although the pain may last for as long as 24?hr. The pain may inhibit daily activity, because physical activity aggravates the pain. A characteristic feature of childhood migraine is intense nausea and vomiting, which may be more bothersome than the headache. The vomiting may be associated with abdominal pain and fever; thus, conditions such as appendicitis and a systemic infection may be erroneously confused with the primary diagnosis. Additional symptoms include extreme paleness, photophobia, lightheadedness, phonophobia, osmophobia (aversion to odors), and paresthesias of the hands and feet. A family history, particularly on the maternal side, is present in approximately 90% of children with common migraine. Thus, considerable caution should be exercised when making the diagnosis of a common migraine in the absence of a positive family history.

Additional features of all migraines may include near synchrony with perimenstrual or periovulation timing, gradual appearance after sustained exercise, relief with sleep, stereotypical prodromes (hypersomnia, food craving, irritability, moodiness), precipitation by food or odors, and onset after a letdown or high period of stress. Manifestations suggestive of a more serious condition include rapid onset of the first or worst headache of the patient's life, a change in the characteristics of the headaches, a progressive headache lasting for days, headache associated with Valsalva maneuver, chronic systemic signs (weight loss, fever), persistent focal neurologic manifestations, seizures, loss of consciousness, nuchal rigidity, cranial bruits, abnormal visual fields, or papilledema (Box 588–1).

CLASSIC MIGRAINE (MIGRAINE WITH AN AURA).

In this disorder, an aura precedes the onset of the headache. Visual auras are rarely present in young children with migraine, but when they occur they may take the form of blurred vision, scotoma (an area of depressed vision within the visual field), photopsia (flashes of light), fortification spectra (brilliant white zigzag lines), or irregular distortion of objects. Some patients also have vertigo and lightheadedness during this stage of the headache. Sensory symptoms include perioral paresthesias and numbness of the hands and feet. Distortions of body image may

Box 588.1-1. Indications for Neuroimaging in a Child with Headaches

Abnormal neurologic signs

Recent school failure, behavioral change, fall-off in linear growth rate

Headache awakens child during sleep; early morning headache, with increase in frequency and severity

Periodic headaches and seizures coincide, especially if seizure has a focal onset

Migraine and seizure occur in the same episode, and vascular symptoms precede the seizure (20–50% risk of tumor or arteriovenous malformation)

Cluster headaches in child; any child <5 or 6 yr whose principal complaint is a headache

Focal neurologic symptoms or signs developing during a headache (i.e., complicated migraine)

Focal neurologic symptoms or signs (except classic visual symptoms of migraine) develop during the aura, with fixed laterality; focal signs of the aura persisting or recurring in the headache phase

Visual graying out occurring at the peak of a headache instead of the aura

Brief cough headache in a child or adolescent

Brief cough headache in a child or adolescent

Modified from Barlow CF: Headaches and Migraine in Childhood. Philadelphia, JB Lippincott, 1984, p 205.

predominate as a prelude to a classic migraine headache. After the aura, a patient with classic migraine develops typical symptoms of a common migraine as described earlier.

MIGRAINE VARIANTS.

These variants include cyclic vomiting, acute confusional states, and benign paroxysmal vertigo. The last condition is discussed in Chapter 587 . *Cyclic vomiting* is characterized by recurrent, sometimes monthly bouts of severe vomiting that may be so intense that dehydration and electrolyte abnormalities occur, particularly in infants. Systemic manifestations such as fever, abdominal pain, and diarrhea are initially absent, but they may become prominent in association with excessive fluid losses secondary to vomiting. The vomiting may be protracted and persist for several days. The child may appear pale and frightened but does not lose consciousness. After a period of deep sleep, the child awakens and resumes normal play and eating habits as if the vomiting had not occurred. Many children with cyclic vomiting have a positive family history of migraine, and as they grow older and become verbal, they describe a typical migraine headache that leaves little doubt about the diagnosis and the association of the cyclic vomiting with the condition. Cyclic vomiting is treated with rectally administered antiemetics such as dimenhydrinate or ondansetron and careful attention to fluid replacement if the vomiting is excessive. Additional causes of cyclic vomiting include intestinal obstruction (e.g., malrotation, intermittent volvulus, duodenal web, duplication cysts, superior mesenteric artery compression, and internal hernias), peptic ulcer, gastritis, giardiasis, chronic pancreatitis, and Crohn disease. Abnormal gastrointestinal motility and pelviureteric junction obstruction also can cause cyclic vomiting. Metabolic causes include disorders of amino acid metabolism (i.e., heterozygote ornithine transcarbamylase deficiency), organic acidurias (e.g., propionic acidemia, methylmalonic acidemia), fatty acid oxidation defects (e.g., medium-chain acyl-CoA dehydrogenase deficiency), disorders of carbohydrate metabolism (e.g., hereditary fructose intolerance), acute intermittent porphyria, and structural central nervous system (CNS) lesions (e.g., posterior fossa brain tumors, subdural hematoma or effusions).

Acute confusional states may also be a manifestation of migraine. Migraine may present in a bizarre fashion, particularly in children, characterized by confusion, hyperactivity, disorientation, unresponsiveness, memory disturbances, vomiting, and lethargy. The neurologic examination shows defects of the sensorium, delayed responses to stimuli including touch and pain, and occasionally plantar extensor responses. The differential diagnosis includes toxic (drugs of abuse, ingestions) encephalopathy (particularly in an adolescent), encephalitis, acute psychosis, postictal state, petit mal (absence) status epilepticus, head trauma, and sepsis. The episode of acute confusion may persist for several hours and characteristically clears spontaneously after sleep; patients have no recall of the confusional state. The diagnosis is usually made in retrospect as a patient or family recalls the onset of a severe headache or visual symptoms preceding the acute attack of confusion, and a family history of migraine is established. Acute confusional states as a component of migraine probably result from localized cerebral edema due to increased vascular permeability during the headache. The electroencephalogram (EEG) shows regional areas of slowing (2–4 cps) during and shortly after the attack but routinely returns to normal within a few days.

COMPLICATED MIGRAINE.

Complicated migraine refers to the development of neurologic signs during a headache that persist after termination of the headache. The presence of neurologic signs in association with a headache suggests the possibility of an underlying structural lesion and requires a thorough investigation. There are three subsets of complicated migraine.

Brainstem signs predominate in patients with *basilar migraine* because of vasoconstriction of the basilar and posterior cerebral arteries. The major symptoms include vertigo, tinnitus, diplopia, blurred vision, scotoma, ataxia, and an occipital headache. The pupils may be dilated, and ptosis may be evident. Alterations in consciousness followed by a generalized seizure may result. After the attack there is a complete resolution of the neurologic symptoms and signs. Most affected children have a strongly positive family history of migraine. Many develop classic migraine as adolescents or adults. Relatively minor head trauma may precipitate an episode of basilar migraine. The condition has been described in children of both sexes, with girls younger than 4 yr being at particular risk.

Ophthalmoplegic migraine is relatively rare in children. These patients develop a third-nerve palsy ipsilateral to the headache during the attack, which is caused by altered blood supply to the oculomotor nerve. The major differential diagnosis is a congenital aneurysm compressing the oculomotor nerve. *Amaurosis fugax* (acute, reversible, monocular blindness) may also be a variant of complicated migraine.

Hemiplegic migraine is characterized by the onset of unilateral sensory or motor signs during an episode of migraine. Hemisyndromes are more common in children than in adults and may be characterized by numbness of the face, arm, and leg; unilateral weakness; and aphasia. More than one attack is uncommon in the pediatric age group. The neurologic signs may be transient or may persist for days. It is unusual for a child to develop a completed stroke after a single episode. Hemiplegic migraine in an older child or adolescent has a relatively good prognosis, and a positive family history of similar hemiplegic events is often elicited. Familial hemiplegic migraine (FHM) is an autosomal dominant disorder. FHM is characterized by hemiplegia during the headache and, in some kindreds, progressive cerebellar atrophy. Mutations of the CACNL1A4 gene located on chromosome 19p13.1 are found in the majority of patients with FHM. Additional mutations may be identified in the calcium channel gene CACNL1A4, which would establish the genetic basis of the more common types of migraine.

Some children with migraine develop the syndrome of *alternating hemiplegia*, which has its onset during infancy. Acute hemiplegia may be the initial manifestation of migraine and may recur, affecting one side and then the other. Frequent episodes of vasoconstriction associated with ischemia may result in irreversible cerebral injury leading to mental retardation and epilepsy in this subgroup of children.

Diagnosis and Differential Diagnosis.

A thorough history and physical examination suffice to establish the diagnosis in most

cases. Basilar migraine may be confused with several conditions, including congenital malformations of the skull and cervical vertebrae, posterior fossa tumors, toxins and drugs, and metabolic abnormalities including Leigh disease and pyruvate decarboxylase deficiency. In children with hemiplegic migraine, an arteriovenous malformation, MELAS (mitochondrial myopathy, encephalopathy, lactic acidosis, and stroke), cerebral tumor, Todd paralysis, clotting disorders, hemoglobinopathies such as sickle cell disease, and metabolic conditions including homocystinuria should be considered. A lipid profile should be obtained in children with migraine and a positive family history of premature myocardial infarction or cerebrovascular accident. Migraines may occur in patients with systemic lupus erythematosus and patients abusing cocaine. The organization of laboratory tests and radiologic studies depends on the constellation of symptoms and findings during the neurologic examination. A CT or MRI study is indicated if the headache is associated with an unusual constellation of symptoms or signs (see earlier) or when increased ICP is suspected (see Box 588–1).

Treatment.

Migraine may be prevented or ameliorated by *avoiding certain initiating stimuli*. A few children can identify specific factors that uniformly result in a headache. The most common precipitators of migraine headaches are stress, fatigue, and anxiety. An affected child may be under undue stress because of difficulties at home or school, particularly when unrealistic pressures or demands are placed on the patient. Children who experience recurrent migraine headaches during the school year may have a learning disability or may have been placed in a too highly competitive classroom. Reassessment of the child's school placement and academic abilities may be the most important step in the management of the headache disorder. Some studies implicate certain foods as a cause of migraine, particularly nuts, chocolate, cola drinks, hot dogs, spicy meats, kippers, and Chinese food (monosodium glutamate). Elimination of the incriminating foodstuff is indicated if the history suggests a relationship between the ingestion of a particular food and the onset of headache. Avoidance of bright flashing lights, sun exposure, excessive physical exertion, mild head trauma, loud noises, hunger, fatigue, motion sickness, and drugs (including alcohol and oral contraceptives) is indicated when the history suggests a direct relationship. The frequency and severity of migraine headaches are reduced significantly in at least 50% of pediatric patients who undergo a careful history and neurologic examination followed by reassurance from the physician.

Management of an acute attack of migraine should include the use of *analgesics* and *antiemetics*. Most migraine headaches in children can be treated by the judicious use of *acetaminophen* or *ibuprofen*, particularly if the headaches are mild, infrequent, and of short duration. Additional agents for more severe migraine include naproxen, ketorolac, codeine, butorphanol, and meperidine. The *ergotamine preparations* (ergotamine tartrate or dihydroergotamine) should be considered for older children and adolescents with severe, classic migraine headaches and are most efficacious during the early stages of the migraine attack. The usual dose is 1?mg, which may be administered orally, subcutaneously, or per rectum in the form of a suppository. A repeat dose may be given 30?min later. Ergotamine should not be prescribed for patients with hemiplegic episodes. The ergotamines are frequently ineffective in children because they must be used early in the evolution of the headache. Most children either are unaware of an aura or fail to communicate the onset of the headache to their parents. An antiemetic such as *dimenhydrinate*, 5?mg/kg/24?hr in four divided doses, is the mainstay of treatment when vomiting is the major symptom. The child usually prefers to rest in a quiet, darkened room and typically awakens, refreshed and headache free, several hours later after a deep sleep. *Sumatriptan*, a specific and selective 5-hydroxytryptamine receptor agonist, is effective in treating the acute phase of both classic and common migraine headaches in adults. The drug may be administered subcutaneously, nasally, or orally, and the adverse effects, including hot flushes, nausea and vomiting, fatigue, and drowsiness, are usually minor and transient. In one well-controlled study, a 20?mg dose of sumatriptan administered by nasal spray was effective and well tolerated in treating acute migraine in adolescents. Hypertension and coronary vasospasm have been reported in adults. The drug is not licensed at present for patients younger than 18 yr. Studies in young children have shown that sumatriptan is much less effective than in adolescents and adults and that there is no difference between the drug and placebo.

Children may develop severe intractable migraine attacks or status migrainosus, which are unresponsive to conventional drug regimens. *Chlorpromazine* is a useful drug in the short term (5–6 days) to “break-up” the migraine. The dose is 2?mg/kg/24?hr PO divided every 4–6?hr or 4?mg/kg/24?hr per rectum divided every 6–8?hr. Intravenous chlorpromazine, 0.5–1.0?mg/kg/dose every 6–8?hr, is often effective in the management of acute migraine in an ambulatory setting. In one study, intravenous *prochlorperazine*, 0.13–0.15?mg/kg, was highly effective in aborting intractable migraine in children with no significant side effects.

The decision to use *continuous daily medication* is based on the severity and frequency of the headaches and on the impact of the migraine on the child's daily activities, including school attendance and performance as well as participation in recreation. The use of prophylactic drugs should be considered if a child experiences more than two to four severe episodes monthly or is unable to attend school regularly. Although few drugs have been subjected to well-designed clinical trials in children, propranolol, a ß-adrenergic blocker, is the drug of choice in most centers. The dose of propranolol is 10–20?mg tid (beginning with 10?mg/24?hr and gradually increasing the drug to the maximum dose or until the desired therapeutic effect is achieved) in children 7–8 yr and older. A common mistake is to discontinue the drug prematurely, because it often takes several weeks to a month until the drug is effective. Additional ß-blockers include atenolol, metoprolol, and nadolol. Other drugs used for migraine prophylaxis include calcium channel blockers (flunarizine, verapamil), tricyclic antidepressants (amitriptyline, nortriptyline), nonsteroidal anti-inflammatory agents, and serotonin receptor antagonists (methysergide [not used in children younger than age 10 yr and not for more than 3 mo because retroperitoneal or pulmonary fibrosis has been reported following 6 mo of continuous use] or pizotyline). If a drug is effective, it is usually maintained for 1 yr, particularly

during the school term.

Behavior management is an effective method for the treatment of migraine in some children and adolescents. Biofeedback and self-hypnosis are replacing pharmacologic treatment in some centers because of the undesirable side effects of drugs and the concern that some may produce chemical dependency. Biofeedback can be mastered by most children older than 8 yr and has been effective in many clinical trials. Several studies of migrainous children show a significant decrease in frequency and no change in intensity of headaches in those treated by self-hypnosis compared with those taking the placebo or propranolol. Many pediatric headache clinics employ social workers skilled in pain management. Children respond favorably to being taught imagery and may often learn to control the pain associated with migraine without the use of medication.

588.2 Organic Headaches

A headache may be the earliest symptom of increased ICP. The headache results from tension or traction of the cerebral blood vessels and dura and occurs initially in a sporadic fashion, primarily

in the early hours in the morning or shortly after the patient arises. The headache is diffuse and generalized and is more prominent over the frontal and occipital regions. Its onset may be insidious, and the pain is enhanced by any activity that elevates the ICP (e.g., coughing, sneezing, or straining during a bowel movement). As the ICP increases, the child becomes lethargic and irritable, and the headache becomes constant. Early morning vomiting is often associated with increased ICP. Causes of organic headaches in children include brain tumors, particularly those located in the posterior fossa, hydrocephalus, meningitis and encephalitis, cerebral abscess, subdural hematoma, chronic lead poisoning, and pseudotumor cerebri. Additional causes of organic headaches in children that may not be associated with increased ICP include arteriovenous malformations, berry aneurysm, collagen vascular diseases affecting the CNS, hypertensive encephalopathy, acute subarachnoid hemorrhage, and stroke. The management of organic headaches depends on the cause. The initial step includes a thorough history and physical examination, including recording of the blood pressure and inspection of the eyegrounds. Ordering of laboratory tests and neuroradiologic procedures depends on the clues provided by the history and physical examination.

588.3 Tension or Stress Headaches

Stress or tension headaches are relatively uncommon in the pediatric age group, particularly before puberty, and are often difficult to differentiate from migraine headaches. The two are often associated in the same patient. Tension headaches infrequently appear in the morning hours but are most apparent during the school day, particularly coinciding with a test or similarly anxiety-provoking circumstance. Although these headaches can be continuous and persist for weeks, they tend to wax and wane and build in intensity during the day. The headache is described as hurting or aching but is rarely perceived as throbbing. Most tension headaches in children are distributed in the frontal region, but they may localize over the vertex or the occipital area. Unlike migraine or headaches associated with increased ICP, tension headaches are not, as a rule, associated with nausea and vomiting.

The *diagnosis* of tension headache is made by exclusion at the completion of the history and physical examination. Studies such as an EEG or a CT scan are rarely necessary. Management consists of a search for possible underlying emotional or stressful factors. Most children have considerable insight into the origin of tension headaches and, when given the opportunity, will share concerns and conflicts. A poor self-image, fear of school failure, and lack of self-confidence are common factors. A depressed child occasionally presents with severe headaches. These patients may also complain of sudden mood changes, weight loss, anorexia, disturbed sleep, fatigue, and withdrawal from social activities.

Treatment of tension headaches begins with reassurance and an explanation about how stress may cause a headache. Anxiety and stress may unconsciously produce constant isometric contraction of the temporalis, masseter, or trapezius muscles, which leads to the characteristic dull, aching headache. Steps should be introduced to remove obvious anxiety-provoking situations. Acetaminophen and other mild analgesics are often all that are required to treat a tension headache. Sedatives and antidepressants are rarely necessary. Children with severe tension headaches may benefit from a brief hospitalization, particularly if an underlying depressive illness is under consideration. In the hospital setting, the child's interaction with other patients, nursing and medical staff, and family is observed while a plan is formulated for counseling or psychiatric intervention. In most cases, the child's headaches are considerably relieved during the period of observation. As with migraine headaches, biofeedback and self-hypnosis exercises are effective in the treatment of some patients with tension headaches.

Chapter 589 - Neurocutaneous Syndromes

Robert H. A. Haslam

The neurocutaneous syndromes include a heterogeneous group of disorders characterized by abnormalities of both the integument and central nervous system (CNS). Most disorders are familial and believed to arise from a defect in differentiation of the primitive ectoderm. Disorders classified as neurocutaneous syndromes include neurofibromatosis, tuberous sclerosis, Sturge-Weber disease, von Hippel-Lindau disease, ataxia telangiectasia, linear nevus syndrome, hypomelanosis of Ito (see Chapter 643), and incontinentia pigmenti (see Chapter 642).

589.1 Neurofibromatosis

Neurofibromatosis (NF), von Recklinghausen disease, is a common autosomal dominant disorder. The condition is protean, because virtually every system and organ may be affected, and progressive in that distinctive features may be present at birth but the development of complications is delayed for decades. NF is the consequence of an abnormality of neural crest differentiation and migration during the early stages of embryogenesis (see also Chapter 642).

Clinical Manifestations and Diagnosis.

There are two distinct forms of NF. NF-1 is the most prevalent type, with an incidence of 1/4,000, and is diagnosed when any two of the following signs are present. (1) *Six or more café-au-lait macules over 5?mm in greatest diameter in prepubertal individuals and over 15?mm in greatest diameter in postpubertal individuals*. Café-au-lait spots are the hallmark

of neurofibromatosis and are present in almost 100% of patients. They are present at birth but increase in size, number, and pigmentation, especially during the first few years of life. The spots are scattered over the body surface, with predilection for the trunk and extremities, with sparing of the face. (2) *Axillary or inguinal freckling* consists of multiple hyperpigmented areas 2–3?mm in diameter. (3) *Two or more iris*

Lisch nodules. Lisch nodules are hamartomas located within the iris and are best identified with a slit-lamp examination. They are present in more than 74% of patients with NF-1 but are not a component of NF-2. The prevalence of Lisch nodules increases with age, from only 5% of children younger than 3 yr of age, to 42% among children 3–4 yr of age, to 100% of adults 21 yr of age or older. (4) *Two or more neurofibromas or one plexiform neurofibroma*. Neurofibromas typically involve the skin, but they may be situated along peripheral nerves and blood vessels and within viscera including the gastrointestinal tract. These cutaneous lesions appear characteristically during adolescence or pregnancy, suggesting a hormonal influence. They are usually small, rubbery lesions with a slight purplish discoloration of the overlying skin. Plexiform neurofibromas are usually evident at birth and result from diffuse thickening of nerve trunks that are frequently located in the orbital or temporal region of the face. The skin overlying a plexiform neurofibroma may be hyperpigmented to a greater degree than a café-au-lait spot. Plexiform neurofibromas may produce overgrowth of an extremity and a deformity of the corresponding bone. (5) *A distinctive osseous lesion* such as sphenoid dysplasia (which may cause pulsating exophthalmos) or cortical thinning of long bones with or without pseudoarthrosis. Scoliosis is the most common orthopedic manifestation of NF-1, although it is not specific enough to be included as a diagnostic criterion. (6) *Optic gliomas* are present in approximately 15% of patients with NF-1. These relatively benign tumors consist of glial cells and a mucinous material. Most patients with optic gliomas are asymptomatic and have normal or near-normal vision, but approximately 20% have visual disturbances or evidence of precocious sexual development secondary to tumor invasion of the hypothalamus. Children rarely are aware of unilateral visual loss; thus, diagnosis may be delayed. Patients with a unilateral optic glioma typically display an afferent pupillary defect. To test for this, each eye is alternately stimulated by a bright light source (swinging flashlight test). The affected pupil dilates rather than constricts, whereas light in the unaffected eye causes both pupils to constrict equally. Patients with NF-1 and a plexiform neuroma of the eyelid have a high association with an ipsilateral optic glioma. The MRI findings of an optic glioma include diffuse thickening, localized enlargement, or a distinct focal mass originating from the optic nerve or chiasm. (7) *A first-degree relative with NF-1 whose diagnosis was based on the aforementioned criteria*. The majority of mutations in NF-1 occur in the paternal germline. The NF-1 gene on chromosome region 17q11.2 encodes all mRNA of 11–13?kb containing at least 59 exons that produces a protein neurofibromin.

Children with NF-1 are susceptible to *neurologic complications*. MRI studies of selected children have shown abnormal signals in the globus pallidus, thalamus, and internal capsule. These probably represent low-grade glioma or hamartoma that is not detected by CT scanning (Fig. 589–1). These findings may account for the high incidence of learning disabilities, attention deficit disorders, and abnormalities of speech among affected children. Complex partial and generalized tonic-clonic seizures are a frequent complication. Hydrocephalus is a rare manifestation secondary to aqueductal stenosis, whereas macrocephaly with normal-sized ventricles is a common finding. The cerebral vessels may develop stenosis, aneurysms, or stenosis resulting in moyamoya disease (see Fig. 593–1). Neurologic sequelae include transient cerebrovascular ischemic attacks, hemiparesis, and cognitive defects. Not surprisingly, *psychologic disturbances*

Figure 589.1-1 T2 weighted MRI scan of a patient with neurofibromatosis. Note the high-signal areas in the basal ganglia (*black arrows*), which represent hamartomas.

are prevalent owing to the seriousness and uncertainty of the disease. Precocious puberty may become evident in the presence or absence of lesions of the optic chiasm and hypothalamus. *Malignant neoplasms* are also a significant problem in patients with NF-1. A neurofibroma occasionally differentiates into a neurofibrosarcoma or malignant schwannoma. Patients with NF-1 are at risk for hypertension, which may result from renal vascular stenosis or a pheochromocytoma. The incidence of pheochromocytoma, rhabdomyosarcoma, leukemia, and Wilms' tumor is higher than in the general population. There is an unusual association involving myeloid leukemia, juvenile xanthogranuloma, and NF-1. However, tumors of the CNS (including optic gliomas, meningiomas of the brain and spinal cord, neurofibromas, astrocytomas, and neurilemmomas) account for significant morbidity and mortality because of their increased frequency in patients with NF-1.

NF-2 accounts for 10% of all cases of NF, with an incidence of 1/50,000, and may be diagnosed when one of the following is present: (1) *Bilateral eighth nerve masses* consistent with acoustic neuromas as demonstrated by CT scanning or MRI. (2) *A parent, sibling, or child with NF-2* and either unilateral eighth nerve masses or any two of the following: neurofibroma, meningioma, glioma, schwannoma, or juvenile posterior subcapsular lenticular opacities. **Bilateral acoustic neuromas** are the most distinctive feature of NF-2. Symptoms of hearing loss, facial weakness, headache, or unsteadiness may appear during childhood, although signs of a cerebellopontine angle mass are more commonly present in the 2nd and 3rd decades of life. Although café-au-lait spots and skin neurofibromas are classic findings in NF-1, they are much less common in NF-2. Posterior subcapsular lens opacities are identified in approximately 50% of patients with NF-2. As with NF-1, CNS tumors, including Schwann cell and glial tumors, and meningiomas are common in patients with NF-2. Linkage analysis has shown that the gene for NF-2 is located near the center of the long arm of chromosome 22q1.11.

Treatment.

Because there is no specific treatment for NF, management includes genetic counseling and early detection of treatable conditions or complications. The National Institutes of Health (NIH) consensus statement suggests that tests should be dictated by findings on clinical evaluation. Laboratory tests in asymptomatic patients are unlikely to be of value, particularly evoked potentials, an electroencephalogram (EEG), CT, or MRI. There is a lack of consensus concerning the indications for neuroimaging studies in NF-1, although there is unanimous agreement that all symptomatic cases (i.e., visual loss or disturbance, proptosis, symptoms and signs of increased intracranial pressure) must be studied without delay. The NIH Consensus Development Conference advised against routine imaging studies, because treatment in these asymptomatic NF-1 children is rarely required. It is recommended that the child have a detailed history and physical examination by a pediatrician and a thorough annual ophthalmologic examination by a pediatric ophthalmologist. A parent with NF has a 50% chance of transmitting the disease with each pregnancy. The type of NF (NF-1 and NF-2) “breeds true” for successive

generations. Because approximately half of all cases of NF result from fresh mutations, each parent should be carefully examined (including a search for Lisch nodules) before counseling for the risk of affected future pregnancies. Standard DNA diagnostic analysis is not practical for the prenatal diagnosis of the NF-1 gene because of the large size of the gene and the significant number of mutations. However, prenatal diagnosis is feasible if the mutation causing the condition is known in the affected parent. The majority of NF-2 cases are the result of a mutation. Examination of fetal DNA for the characteristic single-strand conformational polymorphism of an altered DNA sequence provides accurate prenatal testing. In familial cases, when affected and unaffected family members are available, linkage can be established, making prenatal diagnosis available with a certain degree of accuracy.

589.2 Tuberous Sclerosis

Tuberous sclerosis (TS) is inherited as an autosomal dominant trait with an estimated frequency of 1/6,000. Molecular genetic studies have identified two foci for the TS complex. In TSC 1, the abnormality is located on chromosome 9q34, and in TSC 2, the genetic abnormality is on chromosome 16p13. At least half of the cases are sporadic owing to new mutations. The 8.6-kb TSC_1 transcript encodes a protein of 130?kd called *hamartin*. The TSC_2 gene encodes the protein *tuberin*. TS is an extremely heterogeneous disease with a wide clinical spectrum varying from severe mental retardation and incapacitating seizures to normal intelligence and a lack of seizures, often within the same family. As a rule, the younger the patient presents with symptoms and signs of TS, the greater is the likelihood of mental retardation. The disease affects many organ systems other than the skin and brain, including the heart, kidney, eyes, lungs, and bone.

Pathology.

The characteristic brain lesions consist of tubers. Tubers are located in the convolutions of the cerebral hemispheres and are typically present in the subependymal region, where they undergo calcification and project into the ventricular cavity, producing a candle-dripping appearance. Tubers in the region of the foramen of Monro may cause obstruction of cerebrospinal fluid (CSF) flow and hydrocephalus. The microscopic appearance of the tuber consists of decreased numbers of neurons, a proliferation of astrocytes, and the presence of oddly shaped multinucleated giant neurons. MRI is useful for identification of the lesions. Generally, the greater the number of tubers, the more neurologically impaired is the patient.

Clinical Manifestations.

TS may present during infancy with infantile spasms and a hypsarrhythmic EEG pattern. Careful examination of the skin on the trunk and extremities shows the typical hypopigmented skin lesions that have been likened to an ash leaf in more than 90% of cases in this age group. Visualization of the hypopigmented lesions is enhanced by the use of a Wood ultraviolet lamp (see Chapter 545). The CT scan typically shows calcified tubers in the periventricular area, but these may not be apparent until 3–4 yr of age (Fig. 589–2). The seizures may be difficult to control, and at a later age they may develop into myoclonic epilepsy. In Europe and Canada, infantile spasms associated with TS are often treated with vigabatrin (rather than adrenocorticotropic hormone), with good results. Vigabatrin is not available in the United States. There is a high incidence of mental retardation in young patients with

TS and infantile spasms.

During childhood, TS presents most often with a generalized seizure disorder and pathognomonic skin lesions. Sebaceous adenomas develop between 4 and 6 yr of age; they appear as tiny red nodules over the nose and cheeks and are sometimes confused with acne. Later, they enlarge, coalesce, and assume a fleshy appearance. A *shagreen patch* is also characteristic of TS and consists of a roughened, raised lesion with an orange-peel consistency located primarily in the lumbosacral region. Subungual or periungual fibromas arise from the stratum lucidum of the finger and toe in many patients with TS during adolescence. Retinal lesions consist of two types: mulberry tumors that arise from the nerve head or round, flat gray lesions (phakoma) in the region of the disc (Fig. 589–3). Brain tumors are much less common in TS compared with NF, but a tuber occasionally differentiates into a malignant astrocytoma. Approximately 50% of children with TS have rhabdomyomas of the heart, which may be detected in a fetus at risk by an echocardiogram. The rhabdomyomas may be numerous or located at the apex of the left ventricle, and although they can cause congestive heart failure and arrhythmias, they tend to slowly resolve spontaneously. The kidneys in most patients are involved by hamartomas or polycystic disease, resulting in hematuria, pain, and, in some cases, renal failure. Angiomyolipomas may produce generalized cystic or fibrous pulmonary changes in the lung and lead to spontaneous pneumothorax.

Diagnosis.

Diagnosis of TS relies on a high index of suspicion when assessing a child with infantile spasms. A careful search for the typical skin and retinal lesions should be completed in all patients with a seizure disorder. Head CT scan or MRI confirms the diagnosis in most cases.

Treatment.

Management consists of seizure control and baseline studies, including renal ultrasonography, an echocardiogram, and a chest roentgenogram with follow-up as indicated. Symptoms and signs of increased intracranial pressure suggest obstruction of the foramen of Monro by a tuber or malignant transformation of a tuber, and warrant immediate investigation and surgical intervention.

589.3 Sturge-Weber Disease

Sturge-Weber disease consists of a constellation of symptoms and signs including a facial nevus (port-wine stain), seizures, hemiparesis, intracranial calcifications, and, in many cases, mental retardation. It occurs sporadically, with a frequency of approximately 1/50,000.

Etiology.

The condition is thought to result from anomalous development of the primordial vascular bed during the early stages of cerebral vascularization. At this stage, the blood supply to the brain, meninges, and face is undergoing reorganization, while the primitive ectoderm in the region differentiates into the skin of the upper face and the occipital lobe of the cerebrum. The overlying leptomeninges are richly vascularized, and the brain beneath becomes atrophic and calcified, particularly in the molecular layer of the cortex, in patients with Sturge-Weber disease.

Figure 589.3-2 Tuberous sclerosis. *A,* CT scan with subependymal calcifications characteristic of tuberous sclerosis. *B,* The MRI demonstrates multiple subependymal nodules in the same patient (*black arrow*). Parenchymal tubers are also visible on both the CT and the MRI scan as low-density areas in the brain parenchyma.

Figure 589.3-3 An astrocytoma of the retina (mulberry tumor) in a patient with tuberous sclerosis.

Clinical Manifestations.

The facial nevus is present at birth and tends to be unilateral and always involves the upper face and eyelid. The nevus may also be evident over the lower face, trunk, and in the mucosa of the mouth and pharynx. Not all children with facial nevi have Sturge-Weber disease (see Chapter 640). Buphthalmos and glaucoma of the ipsilateral eye are a common complication. Seizures develop in most patients during the 1st year of life. They are typically focal tonic-clonic and contralateral to the side of the facial nevus. The seizures tend to become refractory to anticonvulsants and are associated with a slowly progressive hemiparesis in many cases. Although neurodevelopment appears to be normal during the 1st year of life, mental retardation or severe learning disabilities are present in at least 50% during later childhood, probably the result of prolonged generalized seizures and increasing

cerebral atrophy secondary to local hypoxia and use of numerous anticonvulsants.

Figure 589.3-4 A CT scan of a patient with Sturge-Weber syndrome showing unilateral calcification and atrophy of a cerebral hemisphere.

Diagnosis.

The skull radiograph shows intracranial calcification in the occipitoparietal region in most patients. This characteristically assumes a serpentine or railroad-track appearance. The CT scan highlights the extent of the calcification that is usually associated with unilateral cortical atrophy and ipsilateral dilatation of the lateral ventricle (Fig. 589–4).

Treatment.

Management of Sturge-Weber disease is multifaceted and somewhat controversial. Seizure frequency and the significant risk for mental retardation influence the treatment plan. For patients with well-controlled seizures and normal or near-normal development, management is straightforward and conservative. However, increasing evidence shows that a

hemispherectomy or lobectomy may prevent the development of mental retardation, in patients with recalcitrant seizures, particularly if the surgery is accomplished during the 1st year of life. Because of the risk of glaucoma, regular measurements of intraocular pressure with a tenonometer is indicated. The facial nevus is often a target for ridicule by classmates, leading to psychologic trauma. Flashlamp-pulsed laser therapy holds considerable promise for clearing of the port-wine stain. Finally, because of the high frequency of developmental disabilities, special educational facilities are frequently required.

589.4 von Hippel-Lindau Disease

As with most of the neurocutaneous syndromes, von Hippel-Lindau disease affects many organs, including the cerebellum, spinal cord, medulla, retina, kidney, pancreas, and epididymis. von Hippel-Lindau disease is inherited as an autosomal dominant trait with variable penetrance and delayed expression. The gene for von Hippel-Lindau disease has been mapped to chromosome 3p25. The major neurologic features of the condition include cerebellar hemangioblastomas and retinal angiomata. Patients with cerebellar hemangioblastoma present in early adult life or beyond with symptoms and signs of increased intracranial pressure. A smaller number of patients have hemangioblastoma of the spinal cord, producing abnormalities of proprioception and disturbances of gait and bladder dysfunction. The CT scan typically shows a cystic cerebellar lesion with a vascular mural nodule. Total surgical removal of the tumor is curative. Approximately 25% of patients with cerebellar hemangioblastoma have retinal angiomas.

Retinal angiomas are characterized by small masses of thin-walled capillaries that are fed by large and tortuous arterioles and venules. They are usually located in the peripheral retina so that vision is unaffected. However, exudation in the region of the angiomas may lead to retinal detachment and visual loss. Retinal angiomas are treated with photocoagulation and cryocoagulation, with good results. Cystic lesions of the kidneys, pancreas, liver, and epididymis as well as pheochromocytoma are frequently associated with von Hippel-Lindau disease. Renal carcinoma is the most common cause of death. Regular follow-up and appropriate imaging studies are necessary to identify lesions that may be treated at an early stage.

589.5 Linear Nevus Syndrome

This sporadic condition is characterized by a facial nevus and neurodevelopmental abnormalities. The nevus is located on the forehead and nose and tends to be midline in its distribution. It may be quite faint during infancy but later becomes hyperkeratotic, with a yellow-brown appearance. More than half of the patients have a seizure disorder and are mentally retarded. The seizures may be generalized, myoclonic, or focal motor. Most patients have normal CT studies, although hemimeganencephaly with hamartomatous changes has been reported. Focal neurologic signs including hemiparesis and homonymous hemianopia are more common in this group.

589.6 PHACE Syndrome

Large facial hemangiomas may be associated with a Dandy-Walker malformation, vascular anomalies (coarctation of aorta, aplasia or hypoplastic carotid arteries, aneurysmal carotid dilation, aberrant left subclavian artery), glaucoma, cataracts, microphthalmia, optic nerve hypoplasia, and ventral defects (sternal clefts). There is a female predominance. Airway hemangiomas may produce obstruction. The syndrome denotes *p*osterior fossa malformations, *h*emangiomas, *a*rterial anomalies, *c*oarctation of the aorta and other cardiac defects, and *e*ye abnormalities. Interferon-a is of value in the management of the hemangiomas.

Chapter 590 - Movement Disorders

Michael V. Johnston

Movement disorders cause involuntary movements and/or abnormalities in posture, tone, balance, or fine motor control. The type of movement disorder assists in localizing the pathologic process, whereas the onset, age, and degree of abnormal motor activity and associated neurologic findings help classify the disorder and organize the investigation.

590.1 Ataxias

Ataxia is the inability to make smooth, accurate and coordinated movements, usually due to a disorder of the cerebellum and/or sensory pathways in the posterior columns of the spinal cord. Ataxias may be generalized or primarily affect gait or the hands and arms. *Congenital anomalies* of the posterior fossa, including the Dandy-Walker syndrome, Chiari malformation, and encephalocele, are prominently associated with ataxia because of their destruction or replacement of the cerebellum (see Chapter 585). **Agenesis of the cerebellar vermis** presents in infancy with generalized hypotonia and decreased deep tendon reflexes. Delayed motor milestones and truncal ataxia are typical. A familial variety (Joubert disease) is inherited as an autosomal

recessive trait. Affected children typically have abnormalities of respiration during infancy, characterized by alternating periods of hyperpnea and apnea. In addition to ataxia, mental retardation and abnormal eye movements have been described. MRI is the method of choice for investigating congenital abnormalities of the cerebellum, vermis, and related structures.

The major *infectious causes of ataxia* include cerebellar abscess, acute labyrinthitis, and acute cerebellar ataxia. **Acute cerebellar ataxia** occurs primarily in children 1–3 yr of age and is a diagnosis by exclusion. The condition often follows a viral illness, such as varicella, coxsackievirus, or echovirus infection, by 2–3 wk and is thought to represent an autoimmune response to the viral agent affecting the cerebellum (see Chapters 229 , 232 , and 594). The onset is sudden, and the truncal ataxia can be

so severe that the child is unable to stand or sit. Vomiting may occur initially, but fever and nuchal rigidity are absent. Horizontal nystagmus is evident in approximately 50% of cases, and if the child is able to speak, dysarthria may be impressive. Examination of the cerebrospinal fluid (CSF) is typically normal at the onset of ataxia; however, a slight pleocytosis of lymphocytes (10–30/mm^3) is not unusual. Later in the course, the CSF protein undergoes a moderate elevation. The ataxia begins to improve in a few weeks but may persist for as long as 2 mo. The prognosis for complete recovery is excellent; however, a small number have long-term sequelae, including behavioral and speech disorders as well as ataxia and incoordination. **Acute labyrinthitis** may be difficult to differentiate from acute cerebellar ataxia in a toddler. The condition is associated with middle-ear infections and intense vertigo, vomiting, and abnormalities in labyrinthine function, particularly ice water caloric testing.

Toxic causes of ataxia include alcohol, thallium (which is used occasionally in homes as a pesticide), and the anticonvulsants, particularly phenytoin when serum levels reach or exceed 30?µg/mL (120?µmol/L).

Brain tumors, including tumors of the cerebellum and frontal lobe, as well as neuroblastoma, may present with ataxia. Frontal lobe tumors may cause ataxia owing to destruction of the association fibers connecting the frontal lobe with the cerebellum. Neuroblastoma may be associated with an encephalopathy characterized by progressive ataxia, myoclonic jerks, and opsoclonus (nonrhythmic horizontal and vertical oscillations of the eyes).

Several *metabolic disorders* are characterized by ataxia, including abetalipoproteinemia, arginosuccinic aciduria, and Hartnup disease. **Abetalipoproteinemia** (Bassen-Kornzweig disease) begins in childhood with steatorrhea and failure to thrive (see Chapter 75.3). A blood smear shows acanthocytosis and decreased serum levels of cholesterol and triglycerides, and the serum ß-lipoproteins are absent. Neurologic signs become evident by late childhood and consist of ataxia, retinitis pigmentosa, peripheral neuritis, abnormalities in position and vibration sense, muscle weakness, and mental retardation. Vitamin E is undetectable in the serum of patients with neurologic symptoms.

Degenerative diseases of the central nervous system (CNS) represent an important group of ataxic disorders of childhood because of the genetic consequences and poor prognosis. **Ataxia-telangiectasia,** an autosomal recessive condition, is the most common of the degenerative ataxias and is heralded by ataxia beginning at about age 2 yr and progressing to loss of ambulation by adolescence (see Chapter 116.12). Ataxia-telangiectasia is caused by mutations in the ATM gene located at 11q22-q23. Oculomotor apraxia, defined as having difficulty fixating smoothly on an object and therefore overshooting the target with lateral movement of the head, followed by refixating the eyes, is a frequent finding, as is horizontal nystagmus. The telangiectasia becomes evident by midchildhood and is found on the bulbar conjunctiva, over the bridge of the nose, and on the ears and exposed surfaces of the extremities. Examination of the skin shows a loss of elasticity. Abnormalities of immunologic function that lead to frequent sinopulmonary infections include decreased serum and secretory IgA as well as diminished IgG_2 , IgG_4 , and IgE levels in more than 50% of patients. Children with ataxia-telangiectasia have a 50-to 100-fold greater chance over the normal population of developing lymphoreticular tumors (lymphoma, leukemia, and Hodgkin disease) as well as brain tumors.

Additional laboratory abnormalities include an increased incidence of chromosome breaks, particularly of chromosome 14, and elevated levels of a-fetoprotein. Death results from infection or tumor dissemination.

Friedreich ataxia is inherited as an autosomal recessive trait. The majority of patients are homozygous for a GAA repeat expansion in the noncoding region of the X25 gene, which is located on chromosome 9q13. The gene encodes a 210 amino acid, frataxin. The onset of ataxia is somewhat later than in ataxia-telangiectasia but usually occurs before age 10 yr. The ataxia is slowly progressive and involves the lower extremities to a greater degree than the upper extremities. The Romberg test result is positive; the deep tendon reflexes are absent (particularly the Achilles), and the plantar response is extensor. Patients develop a characteristic explosive, dysarthric speech, and nystagmus is present in most children. Although patients may appear apathetic, their intelligence is preserved. They may have significant weakness of the distal musculature of the hands and feet. Typically noted is a marked loss of vibration and position sense caused by degeneration of the posterior columns and indistinct sensory changes in the distal extremities. Friedreich ataxia is also characterized by skeletal abnormalities, including high-arched feet (pes cavus) and hammer toes, as well as progressive kyphoscoliosis. Results of electrophysiologic studies including visual, auditory brainstem, and somatosensory-evoked potentials are often abnormal. Hypertrophic cardiomyopathy with progression to intractable congestive heart failure is the cause of death for most patients. Several forms of *spinocerebellar ataxia* are similar to Friedreich ataxia. **Roussy-Levy disease** has, in addition, atrophy of the muscles of the lower extremity with a similar pattern of wasting observed in Charcot-Marie-Tooth disease; **Ramsay Hunt syndrome** has an associated myoclonic epilepsy.

The **olivopontocerebellar** atrophies (OPCA) include at least five familial subtypes with dominant inheritance that usually have the onset of ataxia, cranial nerve palsies, and abnormal sensory findings in the 2nd or 3rd decade. However, some cases have been described in children, particularly of Finnish ancestry, with rapidly progressive ataxia, nystagmus, dysarthria, and seizures. Classifications of the hereditary ataxias are based on biochemical analysis; aspartic acid and glutamic acid content in the inferior olive and the Purkinje cell layer of the cerebellum are significantly decreased.

Additional degenerative ataxias include **Pelizaeus-Merzbacher disease,** neuronal ceroid lipofuscinoses, and late onset GM_2 gangliosidosis (see Chapter 592). Rare forms of progressive cerebellar ataxia have been described in association with **vitamin E deficiency.** A number of new inherited forms of progressive ataxia have been defined at the molecular level, including those caused by unstable trinucleotide repeat expansions.

590.2 Chorea, Athetosis, Tremor

Chorea, which means *dance* in Greek, refers to irregular, rapid, uncontrolled, involuntary movements. Choreic movements are often incorporated into semipurposeful acts in an attempt to mask the abnormality or may result in bizarre movements of the hands and arms as well abnormal gait. *Sydenham chorea* is the most common acquired chorea of childhood and is the sole neurologic manifestation of rheumatic fever (see Chapter 168.1).

The pathogenesis is probably an autoimmune response of the CNS to group A streptococcal organisms. The majority of children with Sydenham chorea have antineuronal antibodies, which develop in response to group A ß-hemolytic streptococcal infections. Antineuronal antibodies cross react with the cytoplasm of subthalamic and caudate nuclei neurons. Some pediatric patients with tics and obsessive-compulsive disorder (features also associated with Sydenham chorea) have antineuronal antibodies suggesting that Tourette syndrome and other childhood neuropsychiatric disorders in some cases may be secondary to an autoimmune process. The disorder in these patients has been given the acronym PANDAS (pediatric autoimmune neuropsychiatric disorders associated with streptococcal infections). The primary pathologic findings, possibly the result of the cellular response to antineuronal antibodies, consist of vasculitis of the cortical arterioles with round cell infiltration of the gray and white matter in the surrounding area. The cerebral cortex, caudate nucleus, and subthalamic nuclei are most prominently involved. Chorea is likely a result of functional overactivity of the dopaminergic system.

The three major clinical manifestations of Sydenham chorea include chorea, hypotonia, and emotional lability. The chorea is usually symmetric, although children may have the choreic movements limited to one side of the body. The movements, which are rapid and jerky, are prominent in the face, trunk, and distal extremities and dart from one muscle group to another; they are increased by stress and disappear during sleep. The onset may be abrupt, but the chorea typically has a slowly progressive course. Hypotonia may be a prominent sign, and when combined with severe chorea, the child may be incapable of feeding, dressing, or walking. The speech is often involved and is sometimes unintelligible. Periods of uncontrollable crying and extreme mood swings are characteristic, perhaps in part as a result of the motor handicap and feelings of helplessness. Several typical signs are associated with Sydenham chorea, including the “milkmaid's grip” (relaxing and tightening hand shake), the “choreic hand” (spooning of the extended hand by flexion at the wrist and

extension of the fingers), the “darting tongue” (the tongue cannot be protruded for longer than a few seconds), and the “pronator sign” (the arms and palms turn outward when held above the head). Sydenham chorea may persist for several months and as long as 1–2 yr. About 20% of children experience a recurrence of chorea within 2 yr of the initial episode. Cases with minimal signs are treated conservatively with avoidance of stress as much as possible. Incapacitating chorea is managed with a trial of diazepam followed by valproic acid, phenothiazines, or haloperidol, if the diazepam therapy is unsuccessful.

Although the phenothiazines and haloperidol are effective drugs in the treatment of Sydenham chorea, long-term use may be complicated by the development of another movement disorder, **tardive dyskinesia**. Tardive dyskinesia is characterized by stereotypical facial movements, particularly by lip smacking and protrusion and retraction of the tongue. The movement disorder may gradually disappear but in some patients persists after discontinuing the drug. Because patients with Sydenham chorea are at risk for the development of rheumatic carditis, particularly mitral stenosis, a regimen of daily penicillin prophylaxis should be instituted and maintained until adulthood. A much rarer cause of chorea during childhood, *paroxysmal kinesigenic choreoathetosis*, is discussed in Chapter 587 .

Systemic lupus erythematosus (SLE) may present or be associated with neurologic symptoms and signs including seizures, organic brain syndromes (psychoses), aseptic meningitis, and various isolated neurologic signs including chorea. Chorea may be the presenting sign of SLE, particularly in children. Antiphospholipid antibodies are present in the serum in the majority of these patients. The presence of circulating antiphospholipid antibodies is associated with a high incidence of venous and arterial occlusions. Any child with chorea of unknown cause should be investigated for the possibility of antiphospholipid antibodies.

Huntington disease is a dominantly inherited degenerative disorder of the CNS cause by an expanded sequence of CAG repeats in a gene on chromosome 4p16.3, resulting in mutations in the huntingtin protein. Huntingtin forms abnormal inclusions within the nuclei of neurons and this interaction may sequester and reduce levels of proteins such as CREB binding protein (CBP) needed to activate the transcription of other genes. The onset of symptoms of progressive chorea and presenile dementia occurs most typically between 35 and 55 yr of age. Fewer than 1% of cases begin in children younger than 10 years of age with rigidity, dystonia, and seizures. Mental deterioration and behavioral problems are prominent in children. Generalized tonic-clonic seizures are common and are typically resistant to anticonvulsants. Cerebellar signs are present in 50% and oculomotor apraxia occurs in approximately 20% of cases. The course of the disease is more rapid in children, with an average duration of 8 yr until death compared with 14 yr in adults. CT scanning, although nondiagnostic, shows the mean bifrontal to bicaudate ratio to be decreased, indicating atrophy of the caudate nucleus and putamen. MRI shows hyperdensity of the putamen in adults with the akinetic-rigid form. There is no specific therapy for Huntington disease, but once the diagnosis is confirmed, the pediatrician should provide genetic counseling to the family so that risks for additional cases in future generations are understood. Molecular biologic testing (CAG trinucleotide repeat) is available but is inappropriate for children under the age of consent. Presymptomatic adult patients who test positive respond similarly to patients with cancer when the diagnosis is confirmed.

Other causes of chorea include atypical seizures, drug intoxication (e.g., phenytoin, amitriptyline, and fluphenazine),hormonally induced seizures (e.g., oral contraceptives, pregnancy/ chorea gravidarum), Lyme disease, hypoparathyroidism, hyperthyroidism, and Wilson disease (see Chapter 338.2)

Athetosis or distal writhing movements of the extremities, sometimes combined with chorea (choreoathetosis), is often seen as part of extrapyramidal cerebral palsy caused by asphyxia, kernicterus, or genetic metabolic disorders such as glutaric aciduria. Athetosis is also seen with cerebral palsy associated with prematurity. Chorea and choreoathetosis may also occur after circulatory arrest is used as a support technique for complex cardiac surgery or as a complication of dopamine-blocking neuroleptic drugs such as phenothiazines. Patients with athetosis also often have *rigidity* characterized by muscle stiffness throughout the range of motion in both flexors and extensors in contrast to spasticity in which the increased tone is velocity dependent. Like athetosis and chorea, rigidity results from dysfunction of the basal ganglia, in contrast to spasticity, which reflects upper motor neuron dysfunction.

Tremor is an involuntary movement characterized by rhythmic oscillations of a part of the body, which may be more prominent during rest or with movement. *Jitteriness,* defined as rhythmic tremors of equal amplitude around a fixed axis, is the most common involuntary movement of healthy full-term infants. Jitteriness is most apparent when an infant is crying or being examined (e.g., Moro response) and is abnormal when an infant is awake and alert and when the tremor persists beyond the second week of life. Organic causes of jitteriness include sepsis, intracranial hemorrhage, hypoxic encephalopathy, hypoglycemia, hypocalcemia, hypomagnesemia, prenatal exposure to maternal marijuana, and the narcotic abstinence syndrome. *Essential tremor* is a familial condition, inherited as an autosomal dominant trait. It may begin during childhood and usually is slowly progressive. The tremor has a frequency of 4–9?Hz, primarily affects the distal upper extremities, is typically postural, and commonly disappears with rest. If the tremor causes difficulty in writing or activities of daily living, a trial of propranolol hydrochloride or primidone usually provides a favorable

response. *Primary writing tremor* occurs only during the action of writing and is characterized by a jerky tremor, often responsive to ß–blockers or anticholinergics. Drugs that can cause tremor include amphetamines, valproic acid, neuroleptics, tricyclic antidepressants, caffeine, and theophylline. Tremor may be the initial manifestation of a metabolic disorder, including hypoglycemia, thyrotoxicosis, neuroblastoma, and pheochromocytoma. Children recovering from a severe head injury may develop a proximal tremor that is enhanced by movement and responds to propranolol. Wilson disease often presents with a postural tremor associated with kinetic movement. These patients may also develop a wing-beating tremor of the shoulders when the upper arms are abducted and the elbows flexed. Hereditary dystonia-parkinsonism syndrome often displays a proximal tremor in addition to the characteristic dystonic movements. *Myoclonus,* sudden, brief, jerky, shocklike, involuntary movements, may be superimposed on tremor to cause a myoclonic

tremor as is seen after hypoxic injury to the cerebellum or in certain neurodegenerative diseases.

590.3 Dystonia

Dystonia is a syndrome of sustained muscle contractions, frequently causing twisting and repetitive movements or abnormal postures. Major causes of dystonia include perinatal asphyxia (see Chapters 88.2 and 88.7), kernicterus, generalized primary dystonia, drugs, Wilson disease (hepatolenticular degeneration), and Hallervorden-Spatz disease and numerous other genetic mutations. Dystonia may be a prominent feature of children with extrapyramidal cerebral palsy who have had basal ganglia injury from asphyxia, kernicterus, or insults from metabolic disorders such as glutaric aciduria. Dystonia may develop gradually over many years in older children and teenagers after basal ganglia injury.

Generalized primary dystonia, also referred to as torsion dystonia or *dystonia musculorum deformans* (DMD), is caused by a group of genetic disorders that begin to progress in childhood. One form, which occurs in the Ashkenazi Jewish population, is caused by a dominantly acting mutation in the DYT_1 gene coding for the ATP binding protein Torsin A. The initial manifestation of the disease during childhood is often unilateral posturing of the lower extremity, particularly the foot, which assumes an extended and rotated position, causing tiptoe walking. Because the dystonic movement is initially intermittent and is aggravated by stress, patients are often labeled as hysterical. Ultimately, all four extremities and the axial musculature are affected as well as the muscles of the face and tongue, and thus speech and swallowing become impaired. Other forms of torsion dystonia are caused by mutations in the genes for tyrosine hydroxylase and for epsilon-sarcoglycan, causing the myoclonus dystonia syndrome.

More than a dozen loci for genes for torsion dystonia have been identified. One of these is *dopa-responsive dystonia* (DRD), also called **hereditary progressive dystonia with marked diurnal variation**, or **Segawa disease**. It is inherited as a dominant disorder more common in females. The gene for dopa-sensitive dystonia codes for GTP cyclohydrolase 1, the synthetic enzyme for the cofactor tetrahydrobiopterin that is required for synthesis of the neurotransmitters dopamine and serotonin. The dystonia is usually diurnal, improving with sleep but becoming apparent and sometimes incapacitating during the daytime. However early onset cases can easily be confused with extrapyramidal cerebral palsy. DRD responds remarkably to small daily doses (50–250?mg) of levodopa given with an inhibitor of peripheral catabolism. DRD and dystonia due to mutations in TH can be diagnosed by assaying CSF neurotransmitter metabolites for serotonin and dopamine and biopterin cofactor levels.

Segmental dystonia, including writer's cramp, blepharospasm, and buccomandibular dystonia, is more common in adults and tends to be limited to a specific group of muscles. Segmental dystonia may be seen in patients with genetic forms of torsion

dystonia or may be idiopathic or acquired from overuse of muscles such as in the hands of musicians.

Certain *drugs* are capable of producing an acute dystonic reaction in children. Therapeutic doses of phenytoin or carbamazepine may rarely cause progressive dystonia in children with epilepsy, particularly in those who have an underlying structural abnormality of the brain. Children may have an idiosyncratic reaction to the phenothiazines, characterized by acute dystonic posturing that is sometimes confused with encephalitis. Intravenous diphenhydramine, 1–2?mg/kg/dose, may rapidly reverse the drug-related dystonia. Severe rigidity combined with high fever and delirium may also occur as part of the **neuroleptic malignant syndrome** a few days after starting neuroleptic drugs.

Wilson disease is a rare (incidence of 1/40,000 to 1/100,000 live births) autosomal recessive inborn error of copper transport characterized by cirrhosis of the liver and degenerative changes in the CNS, particularly the basal ganglia (see Chapter 338.2). The gene (WND) for Wilson disease has been mapped to chromosome 13q14-21. It has been determined that there are multiple mutations in the Wilson disease gene, accounting for the variability in presentation of the condition. The precise cause is unknown, but the basic mechanism relates to decreased excretion of biliary copper, owing partly to a lysosomal defect of the liver cells. The initial symptoms and signs in children younger than 10 yr relate to acute or subacute hepatic failure, which is frequently misinterpreted as infectious hepatitis. The neurologic manifestations of Wilson disease rarely appear before age 10 yr, and the initial sign is often progressive dystonia. Tremors of the extremities develop, unilaterally at first, but they eventually become coarse, generalized, and incapacitating (the so-called wing-beating tremor). Signs of progressive basal ganglia destruction include drooling, a fixed smile caused by retraction of the upper lip, dysarthria, dysphonia, rigidity, contractures, dystonia, and choreoathetosis. The Kayser-Fleischer ring, which is best seen with the slit lamp, is pathognomonic and results from deposition of copper in the Descemet membrane. In the untreated state, patients typically become bedridden and demented and die in coma within a few years from the onset of the disease. The MRI or CT scan shows ventricular dilatation in advanced cases with atrophy of the cerebrum and lesions in the thalamus and basal ganglia. The treatment of Wilson disease is discussed in Chapter 338.2 .

Hallervorden-Spatz disease is a rare degenerative disorder inherited as an autosomal recessive trait. Linkage analysis indicates that the gene is located on chromosome 20p13. The condition usually begins during childhood and is characterized by progressive dystonia, rigidity, and choreoathetosis. Spasticity, extensor plantar responses, dysarthria, and intellectual deterioration become evident during adolescence, and death usually occurs by early adulthood. MRI shows lesions of the globus pallidus, including low signal intensity in T2 weighted images (corresponds to iron pigments) and an anteromedial area of high signal intensity, or “eye-of-the-tiger” sign (corresponding to areas of vacuolation). Neuropathologic examination indicates excessive accumulation of iron-containing pigments in the globus pallidus and substantia nigra.

Therapy for dystonia has progressed over the last decade. Children with generalized dystonia, including those with involvement of the muscles of swallowing, may respond to large doses of trihexyphenidyl (Artane). The initial dose is 2?mg/24?hr, slowly increasing to 60–80?mg/24?hr or until untoward side effects (urinary retention, mental confusion, or blurred vision) occur. Additional drugs that have been effective include carbamazepine, levodopa, bromocriptine, and diazepam. Segmental

dystonia such as torticollis often responds well to botulinum toxin injections. Intrathecal baclofen delivered through implantable constant infusion pump may be helpful in some patients. Stereotaxic surgery or electrical deep brain stimulation in the thalamus or globus pallidus also appears to be helpful for some children with severe dystonia.

590.4 Tics

Tics are spasmodic, involuntary, repetitive, stereotyped movements that are nonrhythmic, often exacerbated by stress, and may affect any muscle group. Tics can be classified into three subgroups: transient tics of childhood, chronic tics, and Gilles de la Tourette syndrome (TS). **Transient tic disorder** is the most common movement abnormality of childhood (see Chapter 21). The tics are more prevalent in boys, and the family history is often positive. They consist of eye blinking or facial movements and occasional throat-clearing noises. The disorder persists from weeks to less than a year and does not require drug therapy. **Chronic motor tic disorder** occurs in children and persists throughout adult life. The tics characteristically involve up to three muscle groups simultaneously and may occur throughout life. Evidence shows that the gene for TS may be expressed as simple transient tic of childhood and chronic motor tics, suggesting considerable overlap of these conditions.

Gilles de la Tourette syndrome is a lifelong condition, with a prevalence of approximately 1/2,000, that has an onset between 2 and 21 yr of age(see Chapter 21). TS is probably inherited in most cases as autosomal dominant, and the gene has been tentatively mapped to chromosome 18q22.1. TS is diagnosed in children who have multiple motor tics in different parts of the body with at least one vocal tic beginning before age 21 yr and waxing and waning over a period of more than a year. Obsessive-compulsive behavior and attention deficit hyperactivity disorder (ADHD) are also frequently present. Motor tics are associated with numerous fluctuating movements of the face, eyelids, neck, and shoulders. Ultimately, the tics are accompanied by vocalizations (vocal tics), including throat clearing, sniffling, barking, coprolalia (obscene words), echolalia (repetition of words addressed to the patient), palilalia (repetition of one's own words), and echokinesis (imitation of movement of others). The vocalizations are uncontrollable and frequently jeopardize patients' social interaction with other children. TS is a lifelong condition, and the ultimate prognosis can often be determined by the severity of the symptoms during adolescence.

Medication should be considered when the motor tics or vocalizations interfere significantly with a child's social and academic interactions, although behavior management and biofeedback programs have been successful for some patients. Several reports implicate stimulant medications (methylphenidate) as the cause of TS. Methylphenidate may unmask TS but not cause it. All children who have ADHD and who are treated with stimulant medication should be monitored closely for the onset of tics. The decision to continue the stimulant medication should be determined by the severity of the ADHD and tic disorder. Haloperidol, a dopamine-blocking agent, is effective in the treatment of approximately 50% of children with TS. The initial dose is 0.25?mg/24?hr, and the drug is increased weekly by 0.25?mg to the usual dose range of 2–6?mg/24?hr, although some children can tolerate larger doses. Side effects include cognitive impairment, lethargy, fatigue, depression, restlessness, acute dystonic reactions, drug-induced parkinsonism, akathisia, and tardive dyskinesia syndromes, including tardive dystonia in children. Additional drugs that may prove useful include penfluridol, pimozide, and clonidine. Clonidine, an a_2 -presynaptic noradrenergic agonist, is begun at a dose of 0.05?mg/24?hr and gradually increased to a maximum of 0.125–0.2?mg/24?hr. Several weeks of clonidine therapy may be needed to control the vocal and motor tics. The major side effects are lethargy, fatigue, and drowsiness. Approximately 50% of patients with TS experience obsessive-compulsive symptoms. The tricyclic antidepressant clomipramine is effective in approximately 60% of patients. Other useful antidepressant drugs include sertraline, fluoxetine, and fluvoxamine. Because TS is a chronic disorder associated with many social, behavioral, and learning problems, pediatricians can have an important role in the multidisciplinary management as an advocate for children.

Chapter 591 - Encephalopathies

Michael V. Johnston

Encephalopathy is a generalized disorder of cerebral function that may be acute or chronic, progressive or static. The etiology of the encephalopathies in children includes infectious, toxic (e.g., carbon monoxide, drugs, lead), metabolic, and ischemic causes. Hypoxic-ischemic encephalopathy is discussed in Chapter 88.7 .

591.1 Cerebral Palsy

See also Chapters 37 and 86.2 .

Cerebral palsy (CP) is a diagnostic term used to describe a group of motor syndromes resulting from disorders of early brain development. CP is caused by a broad group of developmental, genetic, metabolic, ischemic, infectious, and other acquired etiologies that produce a common group of neurologic phenotypes. Although it has historically been considered a *static encephalopathy*, this term is now inaccurate because of the recognition that the neurologic features of CP often change or progress over time. In addition, although CP is often associated with epilepsy and abnormalities of speech, vision, and intellect, it is the selective vulnerability of the brain's motor systems that defines the disorder. Many children and adults with CP function at a high educational and vocational level, without any sign of the type of cognitive dysfunction that is generally implied by the term *encephalopathy*.

Epidemiology and Etiology.

CP is the most common and costly form of chronic motor disability that begins in childhood with a prevalence of 2/1000. The Collaborative Perinatal Project, in which approximately 45,000 children were regularly monitored from pregnancy to the age of 7 yr, found that most children with CP had been born at term with uncomplicated labors and deliveries. In 80% of cases, features were identified pointing to antenatal factors causing abnormal brain development. A substantial number of children with CP had congenital anomalies external to the central nervous system (CNS). Fewer

than 10% of children with CP had evidence of intrapartum asphyxia. Intrauterine exposure to maternal infection (e.g., chorioamnionitis, inflammation of placental membranes, umbilical cord inflammation, foul-smelling amniotic fluid, maternal sepsis, temperature greater than 38℃ during labor, and urinary tract infection) is associated with a significant increase in the risk of CP in normal birthweight infants. Another study found elevated levels of inflammatory cytokines in heelstick blood collected at birth from children who later were identified with CP. The prevalence of CP is increased among low birthweight infants, particularly those weighing less than 1,000?g at birth, primarily because of intracerebral hemorrhage and periventricular leukomalacia (PVL). Cramped synchronized general movements may be an early clinical finding in these infants. Although the incidence of intracerebral hemorrhage has declined significantly, PVL remains a major problem. PVL appears to reflect the enhanced vulnerability of immature oligodendroglia in premature infants to oxidative stress caused by ischemia or infectious/inflammatory insults. This information suggests that attempts to reduce the incidence of CP in term born infants should be directed toward increasing understanding of fetal developmental biology and that for premature infants strategies need to be developed to protect the vulnerable developing white matter.

Clinical Manifestations.

CP is generally divided into several major motor syndromes that differ according to the pattern of neurologic involvement, neuropathology, and etiology (Table 591–1). The physiologic classification identifies the major motor abnormality, whereas the topographic taxonomy indicates the involved extremities. CP is also commonly associated with a spectrum of developmental disabilities, including mental retardation, epilepsy, and visual, hearing, speech, cognitive, and behavioral abnormalities. The motor handicap may be the least of the child's problems.

Infants with *spastic hemiplegia* have decreased spontaneous movements on the affected side and show hand preference at a very early age. The arm is often more involved than the leg and difficulty in hand manipulation is obvious by 1 yr of age. Walking is usually delayed until 18–24 mo, and a circumductive gait is apparent. Examination of the extremities may show growth arrest, particularly in the hand and thumbnail, especially if the contralateral parietal lobe is abnormal, because extremity growth is influenced by this area of the brain. Spasticity is apparent in the affected extremities, particularly the ankle, causing an equinovarus deformity of the foot. An affected child often walks on tiptoes because of the increased tone, and the affected upper extremity assumes a dystonic posture when the child runs. Ankle clonus and a Babinski sign may be present, the deep tendon reflexes are increased, and weakness of the hand and foot dorsiflexors is evident. About one third of patients with spastic hemiplegia have a seizure disorder that usually develops during the first year or two, and approximately 25% have cognitive abnormalities including mental retardation. A CT scan or MRI study may show an atrophic cerebral hemisphere with a dilated lateral ventricle contralateral to the side of the affected extremities. An MRI is far more sensitive than CT for most lesions seen with CP, although a CT scan may be useful for detecting calcifications associated with congenital infections. Focal cerebral infarction secondary to intrauterine or perinatal thromboembolism related to thrombophilic disorders, especially anticardiolipin antibodies, is an important cause of hemiplegic CP. Family histories suggestive of thrombosis and inherited clotting disorders may be present and evaluation of the mother may provide information valuable for future pregnancies and other family members.

Spastic diplegia is bilateral spasticity of the legs greater than in the arms. The first indication of spastic diplegia is often noted when an affected infant begins to crawl. The child uses the arms in a normal reciprocal fashion but tends to drag the legs behind more as a rudder (commando crawl) rather than using the normal four-limbed crawling movement. If the spasticity is severe, application of a diaper is difficult because of the excessive

TABLE 591.1-1 -- **Classification of Cerebral Palsy and Major Causes**

Motor Syndrome	Neuropathology	Major Causes
Spastic Diplegia	Periventricular Leukomalacia (periventricular leukomalacic [PVL])	Prematurity Ischemia Infection Endocrine/metabolic (e.g., thyroid)
Spastic quadriplegia	PVL Multicystic encephalomalacia Malformations	Ischemia Infection Endocrine/metabolic Genetic/developmental
Hemiplegia	Stoke: in utero or neonatal	Thrombophilic disorders Infection Genetic/developmental Periventricular hemorrhagic infarction
Extrapyramidal (athetoid, dyskinetic)	Basal ganglia Pathology: putamen, globus pallidus, thalamus	Asphyxia Kernicterus Mitochondrial Genetic/metabolic

adduction of the hips. Examination of the child reveals spasticity in the legs with brisk reflexes, ankle clonus, and a bilateral Babinski sign. When the child is suspended by the axillae, a scissoring posture of the lower extremities is maintained. Walking is significantly delayed, the feet are held in a position of equinovarus, and the child walks on tiptoes. Severe spastic diplegia is characterized by disuse atrophy and impaired growth of the lower extremities and by disproportionate growth with normal development of the upper torso. The prognosis for normal intellectual development is excellent for these patients, and the likelihood of seizures is minimal. The most common neuropathologic finding is periventricular leukomalacia, particularly in the area where fibers innervating the legs course through the internal capsule. MRI is very useful for evaluating the severity of white matter injury and for excluding other brain lesions.

Spastic quadriplegia is the most severe form of CP because of marked motor impairment of all extremities and the high association with mental retardation and seizures. Swallowing difficulties are common as a result of supranuclear bulbar

palsies, often leading to aspiration pneumonia. The most common lesions seen on pathologic examination or on MRI scanning are severe PVL and multicystic cortical encephalomalacia. Neurologic examination shows increased tone and spasticity in all extremities, decreased spontaneous movements, brisk reflexes, and plantar extensor responses. Flexion contractures of the knees and elbows are often present by late childhood. Associated developmental disabilities, including speech and visual abnormalities, are particularly prevalent in this group of children. Children with spastic quadriparesis often have evidence of athetosis and may be classified as having mixed CP.

Athetoid CP, also called *choreoathetoid* or *extrapyramidal* CP, is less common than spastic cerebral palsy. Affected infants are characteristically hypotonic with poor head control and marked head lag and develop increased variable tone with rigidity and dystonia over several years. Feeding may be difficult, and tongue thrust and drooling may be prominent. Speech is typically affected because the oropharyngeal muscles are involved. Speech may be absent or sentences are slurred, and voice modulation is impaired. Generally, upper motor neuron signs are not present, seizures are uncommon, and intellect is preserved in many patients. This form of CP is also referred to as dyskinetic CP in Europe and is the type most likely to be associated with birth asphyxia. Extrapyramidal CP secondary to acute intrapartum near-total asphyxia is associated with bilaterally symmetric lesions in the posterior putamen and ventrolateral thalamus. These lesions appear to be the correlate of the neuropathologic lesion called *status marmoratus* in the basal ganglia. Athetoid CP can also be caused by kernicterus secondary to high levels of bilirubin, and in this case the MRI scan shows lesions in the globus pallidus bilaterally. Extrapyramidal CP can also be associated with lesions in the basal ganglia and thalamus caused by metabolic genetic disorders such as mitochondrial disorders and glutaric aciduria. MRI scanning and possibly metabolic testing are important in the evaluation of children with extrapyramidal CP to make a correct diagnosis of etiology.

Diagnosis.

A thorough history and physical examination should preclude a progressive disorder of the CNS, including degenerative diseases, metabolic disorders, spinal cord tumor, or muscular dystrophy. The possibility of anomalies at the base of the skull or other disorders affecting the cervical spinal cord needs to be considered in patients with little involvement of the arms or cranial nerves. An MRI scan of the brain is generally indicated to determine the location and extent of structural lesions or associated congenital malformations, and an MRI scan of the spinal cord is worthwhile if there is any question about spinal cord pathology. Additional studies may include tests of hearing and visual function. Genetic evaluation should be considered in patients with congenital malformations or evidence of metabolic disorders. Because CP is usually associated with a wide spectrum of developmental disorders, a multidisciplinary approach is most helpful in the assessment and treatment of such children.

Treatment.

A team of physicians from various specialties, as well as occupational and physical therapists, speech pathologists, social workers, educators, and developmental psychologists provide important contributions to the treatment of these children. Parents should be taught how to handle their child in daily activities such as feeding, carrying, dressing, bathing, and playing in ways that limit the effects of abnormal muscle tone. They also need to be instructed in the supervision of a series of exercises designed to prevent the development of contractures, especially a tight Achilles tendon. There is no proof that physical or occupational therapy prevents development of CP in infants at risk or that it corrects the neurologic deficit, but ample evidence shows that therapy optimizes the development of an abnormal child.

Children with spastic diplegia are treated initially with the assistance of adaptive equipment, such as walkers, poles, and standing frames. If a patient has marked spasticity of the lower extremities or evidence of hip dislocation, consideration should be given to performing surgical soft tissue procedures that reduce muscle spasm around the hip girdle, including an adductor tenotomy or psoas transfer and release. A rhizotomy procedure in which the roots of the spinal nerves are divided has produced considerable improvement in selected patients with severe spastic diplegia. A tight heel cord in a child with spastic hemiplegia may be treated surgically by tenotomy of the Achilles tendon. Quadriplegia is managed with motorized wheelchairs, special feeding devices, modified typewriters, and customized seating arrangements.

Communication skills may be enhanced by the use of Bliss symbols, talking typewriters, and specially adapted computers including artificial intelligence computers to augment motor and language function. Significant behavior problems may substantially interfere with the development of a child with CP; their early identification and management are important, and the assistance of a psychologist or psychiatrist may be necessary. Learning and attention deficit disorders and mental retardation are assessed and managed by a psychologist and educator. Strabismus, nystagmus, and optic atrophy are common in children with CP; thus, an ophthalmologist should be included in the initial assessment. Lower urinary tract dysfunction should receive prompt assessment and treatment.

Several drugs have been used to treat spasticity, including dantrolene sodium, the benzodiazepines, and baclofen. These medications are generally ineffective but should be considered if severe spasticity is not controlled by other measures. Intrathecal baclofen has been used successfully in selected children with severe spasticity. This experimental therapy requires a team approach and constant follow-up for complications of the infusion pumping mechanism and infection. Botulinum toxin is undergoing study for the management of spasticity in specific muscle groups, and the preliminary findings show a positive response in those patients studied. Patients with rigidity, dystonia, and spastic quadriparesis sometimes respond to levodopa, and children with dystonia may benefit from carbamazepine or trihexyphenidyl. Hyperbaric oxygen does not improve the condition of children with CP.

591.2 Mitochondrial Encephalomyopathies*

Mitochondrial diseases are a complex family of disorders with many clinical manifestations that can be caused by mutations of nuclear DNA (nDNA) or mitochondrial DNA (mtDNA). They can affect various developmental stages, tissues, or systems,

*Written with the collaboration of Dr. Ingrid Tein.

resulting in a diversity of clinical phenotypes that span all age groups. Biochemically, they can present with a tissue-specific or generalized monoenzymopathy, tissue-specific multienzymopathy, or generalized multienzymopathy. In the respiratory chain, oxidative phosphorylation is mediated by five intramitochondrial enzyme complexes (complexes I–V) that are responsible for producing the adenosine triphosphate (ATP) required for normal cellular function. The maintenance and assembly of oxidative phosphorylation require coordinated regulation of nuclear DNA and mitochondrial DNA genes. Human mtDNA is a small (16.5?kb), circular, double-stranded molecule that has been completely sequenced and encodes 13 structural proteins, all of which are subunits of the respiratory chain complexes, as well as two ribosomal RNAs and 22 tRNAs needed for translation. The nuclear DNA is responsible for synthesizing approximately 70 subunits, transporting them to the mitochondria via chaperone proteins, ensuring their passage across the inner mitochondrial membrane, and coordinating their correct processing and assembly.

mtDNA is unique from nDNA for the following reasons: (1) Its genetic code differs from nDNA, (2) it is tightly packed with information because it contains no introns, (3) it is subject to spontaneous mutations at a higher rate than nDNA, (4) it has less efficient repair mechanisms, and (5) it is present in hundreds or thousands of copies per cell and is transmitted by maternal inheritance. mtDNA is contributed only by the oocyte in the formation of the zygote. If a mutation in mtDNA occurs in the ovum or zygote, it may be passed on randomly to subsequent generations of cells. Some receive few or no mutant genomes (normal or wild-type homoplasmy), others receive a mixed population of mutant and wild-type mtDNAs (heteroplasmy), and others receive primarily or exclusively mutant genomes (mutant homoplasmy). The important implications of maternal inheritance and heteroplasmy are as follows: (1) Inheritance of the disease is maternal, but both sexes are equally affected; (2) phenotypic expression of an mtDNA mutation depends on the relative proportions of mutant and wild-type genomes, with a minimum critical number of mutant genomes being necessary for expression (threshold effect); (3) at cell division, the proportion may shift in daughter cells (mitotic segregation), leading to a corresponding

phenotypic change; and (4) subsequent generations are affected at a higher rate than in autosomal dominant diseases. The critical number of mutant mtDNAs required for the threshold effect may vary, depending on the vulnerability of the tissue to impairments of oxidative metabolism as well as on the vulnerability of the same tissue over time that may increase with aging. Diseases of mitochondrial oxidative phosphorylation can be divided into three groups: (1) defects of nDNA, (2) defects of mtDNA, and (3) defects of communication between the nuclear and mitochondrial genome.

Using a broader classification system, mitochondrial diseases caused by defects of nDNA include defects of substrate transport (plasmalemmal carnitine transporter, carnitine palmitoyltransferase I and II, carnitine acylcarnitine translocase defects), defects of substrate oxidation (pyruvate dehydrogenase complex, pyruvate carboxylase, intramitochondrial fatty acid oxidation defects), defects of the Krebs cycle (a-ketoglutarate dehydrogenase, fumarase, aconitase defects), and defects of the respiratory chain (complexes I to V) including defects of oxidation/phosphorylation coupling (Luft syndrome) and defects of mitochondrial protein transport. These diseases follow mendelian inheritance. Diseases caused by defects of mtDNA can be divided into those due to point mutations that are maternally inherited (Leber hereditary optic neuropathy and MELAS, MERRF, and NARP syndromes—see later text) and those due to deletions or duplications that tend to be sporadic (Kearns-Sayre and Pearson marrow/pancreas syndromes). Finally, diseases caused by defects of communication between the nuclear and mitochondrial genome follow mendelian inheritance and include multiple mtDNA deletions, which are autosomal dominant, and mtDNA depletion syndromes, which are generally autosomal recessive.

Mitochondrial Encephalomyopathy, Encephalomyopathy, Lactic Acidosis, and Strokelike Episodes (MELAS).

Children with MELAS may be normal for the first several years, but they gradually display delayed motor and cognitive development and short stature. The clinical syndrome is characterized by (1) strokelike episodes most commonly in the posterior temporal, parietal, and occipital lobes (with CT or MRI evidence of focal brain abnormalities); (2) lactic acidosis, ragged red fibers (RRF), or both; and (3) at least two of the following: focal or generalized seizures, dementia, recurrent migraine headaches, and vomiting. In one series, onset was before age 15 yr in 62% of patients and hemianopia or cortical blindness was the most common manifestation. Cerebrospinal fluid protein is often increased. The MELAS 3243 mutation can also be associated with different combinations of exercise intolerance, myopathy, ophthalmoplegia, pigmentary retinopathy, hypertrophic or dilated cardiomyopathy, cardiac conduction defects, deafness, endocrinopathy (diabetes mellitus), and proximal renal tubular dysfunction. MELAS is a progressive disorder that has been reported in siblings. It is punctuated with episodes of stroke leading to dementia. Also see Chapter 602.4 .

Regional hypoperfusion can be detected by single-photon-emission CT (SPECT) studies. Neuropathology may show cortical atrophy with infarct-like lesions in both cortical and subcortical structures, basal ganglia calcifications, and ventricular dilatation. Muscle biopsy specimens usually show RRF. Mitochondrial accumulations and abnormalities have been shown in smooth muscle cells of intramuscular vessels and of brain arterioles and in the epithelial cells and blood vessels of the choroid plexus, producing a mitochondrial angiopathy. Muscle biochemistry has shown complex I deficiency in many cases; however, multiple defects have also been documented involving complexes I, III, and IV. Inheritance is maternal, and there is a highly specific, although not exclusive, point mutation at nt 3243 in the $\text{tRNA}^{\text{Leu (UUR)}}$ gene of mtDNA in approximately 80% of patients. An additional 7.5% have a point mutation at nt 3271 in the $\text{tRNA}^{\text{Leu (UUR)}}$ gene. A third mutation has been identified at nt 3252 in the $\text{tRNA}^{\text{leu (UUR)}}$ gene. Because the number of mutant genomes is lower in blood than in muscle, muscle is the preferable tissue for examination.

The prognosis in patients with the full syndrome is poor. Therapeutic trials have included corticosteroids and coenzyme Q10. Lowering the serum lactate concentration with dichloroacetate has led to marked clinical improvement in some cases.

Myoclonus Epilepsy and Ragged-Red Fibers (MERRF).

This syndrome is characterized by progressive myoclonic epilepsy, mitochondrial myopathy, and cerebellar ataxia with dysarthria and nystagmus. Onset may be in childhood or in adult life, and the course may be slowly progressive or rapidly downhill. Other features include dementia, sensorineural hearing loss, optic atrophy, peripheral neuropathy, and spasticity. Because some patients have abnormalities of deep sensation and pes cavus, the condition may be confused with Friedreich ataxia. As with MELAS syndrome, a significant number of patients have a positive family history and short stature. This condition is maternally inherited.

Pathologic findings include elevated serum lactate concentrations, RRF on muscle biopsy, and marked neuronal loss and gliosis affecting in particular the dentate nucleus and inferior olivary complex with some dropout of Purkinje cells and neurons of the red nucleus. Pallor of the posterior columns of the spinal cord and degeneration of the gracile and cuneate nuclei are noted. Muscle biochemistry has shown variable defects of complex III, complexes II and IV, complexes I and IV, or complex IV alone. More than 80% of cases are caused by a heteroplasmic

G to A point mutation at nt 8344 of the tRNA^{Lys} gene of mtDNA. Additional patients have been reported with a T to C mutation at nt 8356 in the tRNA^{Lys} gene.

There is no specific therapy, although coenzyme Q10 appeared to be beneficial in a mother and daughter with the MERRF mutation.

Leber Hereditary Optic Neuropathy (LHON).

LHON is characterized by onset usually between the ages of 18 and 30 yr of acute or subacute visual loss caused by severe bilateral optic atrophy, although children as young as 5 yr have been reported to have LHON. At least 85% of patients are young men. This suggests an X-linked factor that modulates the expression of the mitochondrial DNA point mutation. The classic ophthalmologic features include circumpapillary telangiectatic microangiopathy and pseudoedema of the optic disc. Variable features may include cerebellar ataxia, hyperreflexia, Babinski sign,

psychiatric symptoms, peripheral neuropathy, or cardiac conduction abnormalities (pre-excitation syndrome). Some cases have been associated with widespread white matter lesions as seen with multiple sclerosis. Lactic acidosis and RRF tend to be conspicuously absent in LHON. More than 11 mtDNA point mutations have been described, including a usually homoplasmic G to A transition at nt 11,778 of the ND4 subunit gene of complex I. The latter leads to replacement of a highly conserved arginine residue by histidine at the 340th amino acid and accounts for approximately 50–70% of cases in Europe and more than 90% of cases in Japan. Certain LHON pedigrees with other point mutations are associated with complex neurologic disorders and may have features in common with MELAS syndrome and with infantile bilateral striatal necrosis.

ATPase Subunit 6 Mutation (NARP).

This maternally inherited disorder presents with either Leigh syndrome or with developmental delay, retinitis pigmentosa, dementia, seizures, ataxia, proximal weakness, and sensory neuropathy (NARP syndrome). It is due to a point mutation at nt 8993 within the ATPase subunit 6 gene. The severity of the disease presentation appears to have close correlation with the percentage of mutant mtDNA in leukocytes.

Kearns-Sayre Syndrome (KSS).

The criteria for KSS include a triad of (1) onset before age 20 yr, (2) progressive external ophthalmoplegia (PEO) with ptosis, and (3) pigmentary retinopathy. In addition, there must be at least one of the following: heart block, cerebellar syndrome, or cerebrospinal fluid protein greater than 100?mg/dL. Other nonspecific but common features include dementia, sensorineural hearing loss, and multiple endocrine abnormalities, including short stature, diabetes mellitus, and hypoparathyroidism. The prognosis is poor, despite placement of a pacemaker, and progressively downhill, with death resulting by the 3rd or 4th decade. Unusual clinical presentations can include renal tubular acidosis and Lowe syndrome. There are also a few overlap cases of children with KSS and strokelike episodes. Muscle biopsy shows RRF and variable cytochrome oxidase (COX)-negative fibers. Most patients have mtDNA deletions, and some have duplications. These may be new mutations accounting for the generally sporadic nature of KSS. A few pedigrees have shown autosomal dominant transmission.

Sporadic PEO with RRF is a clinically benign condition characterized by adolescent or young adult–onset ophthalmoplegia, ptosis, and proximal limb girdle weakness. It is slowly progressive and compatible with a relatively normal life. The muscle biopsy material demonstrates RRF and COX-negative fibers. Approximately 50% of patients with PEO have mtDNA deletions, and there is no family history.

Leigh Disease (Subacute Necrotizing Encephalomyopathy).

There are at least four known genetically determined causes of Leigh disease: pyruvate dehydrogenase complex deficiency, complex I deficiency, complex IV (COX) deficiency, and complex V (ATPase) deficiency. These defects may occur sporadically or be inherited by autosomal recessive transmission, as in the case of COX deficiency; by X-linked transmission, as in the case of PDH E_1 a deficiency; or by maternal transmission, as in complex V (ATPase 6 nt 8993 mutation) deficiency. Most cases become apparent during infancy with feeding and swallowing problems, vomiting, and failure to thrive. Delayed motor and language milestones may be evident, and generalized seizures, weakness, hypotonia, ataxia, tremor, pyramidal signs, and nystagmus are prominent findings. Intermittent respirations with associated sighing or sobbing are characteristic and suggest brainstem dysfunction. Some patients have external ophthalmoplegia, ptosis, optic atrophy, and decreased visual acuity. Abnormal results on CT or MRI scan consist of bilaterally symmetric areas of low attenuation in the basal ganglia. Pathologic changes consist of focal symmetric areas of necrosis in the thalamus, basal ganglia, tegmental gray matter, periventricular and periaqueductal regions of the brainstem, and posterior columns of the spinal cord. Microscopically, these *spongiform* lesions show cystic cavitation with neuronal loss, demyelination, and vascular proliferation. Elevations in serum lactate levels are characteristic. The overall outlook is poor, but a few patients experience prolonged periods of remission.

Reye Syndrome.

This encephalopathy, which has become quite uncommon, is associated with pathologic features characterized by fatty degeneration of the viscera (microvesicular steatosis) and mitochondrial abnormalities and biochemical features consistent with a disturbance of mitochondrial metabolism (see Chapter 342). Sporadic Reye syndrome can occur in the context of influenza B virus and salicylate ingestion, in the idiosyncratic valproic acid hepatotoxicity reaction in individuals who may have an underlying genetic predisposition, and in Jamaican vomiting sickness (caused by the hypoglycin toxin).

Recurrent Reye-like syndrome is encountered in children with genetic defects of fatty acid oxidation, such as deficiencies of the plasmalemmal carnitine transporter, carnitine palmitoyltransferase I and II, carnitine acylcarnitine translocase, medium-and long-chain acyl-CoA dehydrogenase, multiple acyl CoA dehydrogenase, and long-chain L-3 hydroxyacyl-CoA dehydrogenase or trifunctional protein. These disorders are manifested by recurrent hypoglycemic and hypoketotic encephalopathy, and they are inherited in an autosomal recessive pattern. Other potential inborn errors of metabolism presenting with Reye syndrome include urea cycle defects (e.g., ornithine transcarbamylase, carbamyl phosphate synthetase) and certain of the organic acidurias (e.g., glutaric aciduria type I), respiratory chain defects, and defects of carbohydrate metabolism (e.g., fructose intolerance).

591.3 Other Encephalopathies

AIDS Encephalopathy.

Encephalopathy is an unfortunate and common manifestation in infants and children with HIV infection (see Chapter 254). Neurologic signs in congenitally infected patients may appear during early infancy or may be delayed to as late as 5 yr of age. The primary features of AIDS encephalopathy include an arrest in brain growth, evidence of developmental delay, and the evolution of neurologic signs including weakness with pyramidal tract signs, ataxia, myoclonus, pseudobulbar palsy, and seizures.

Acute Disseminated Encephalomyelitis (ADEM).

ADEM is a monophasic, immune-mediated illness that follows immunizations or infections including rubeola, rubella, varicella, herpes zoster, mumps, mycoplasma pneumoniae, or other upper respiratory tract infections. Clinical features include lethargy, delirium, coma, seizures, bilateral optic neuritis, myelopathy, and

other focal neurologic signs. MRI typically shows disseminated multifocal lesions in white matter, basal ganglia, and brainstem consistent with edema, inflammation, and demyelination, which may enhance with gadolinium. Hemorrhagic white matter lesions are sometimes seen. Some cases may respond to corticosteroids or immunoglobulin therapy.

Lead Encephalopathy.

See Chapter 703 .

Burn Encephalopathy.

An encephalopathy develops in approximately 5% of children with significant burns during the first several weeks of hospitalization (see also Chapter 62). There is no single cause of burn encephalopathy but rather a combination of factors that include anoxia (smoke inhalation, carbon monoxide poisoning, laryngospasm), electrolyte abnormalities, bacteremia and sepsis, cortical vein thrombosis, a concomitant head injury, cerebral edema, drug reactions, and emotional distress. Seizures are the most common clinical manifestation of burn encephalopathy, but altered states of consciousness, hallucinations, and coma may also occur. Management of burn encephalopathy is directed to a search for the underlying cause and treatment of hypoxemia, seizures, specific electrolyte abnormalities, or cerebral edema. The prognosis for complete neurologic recovery is generally excellent, particularly if seizures are the primary abnormality.

Hypertensive Encephalopathy.

Hypertensive encephalopathy is most commonly associated with renal disease in children, including acute glomerulonephritis, chronic pyelonephritis, and end-stage renal disease (see Chapters 437 and 527). In some cases, hypertensive encephalopathy is the initial manifestation of underlying renal disease. Marked systemic hypertension produces vasoconstriction of the cerebral vessels, which leads to vascular permeability, causing areas of focal cerebral edema and hemorrhage. The onset may be acute, with seizures and coma, or more indolent, with headache, drowsiness and lethargy, nausea and vomiting, blurred vision, transient cortical blindness, and hemiparesis. Examination of the eyegrounds may be nondiagnostic in children, but papilledema and retinal hemorrhages may occur. Treatment is directed at restoration of a normotensive state and control of seizures with appropriate anticonvulsants.

Radiation Encephalopathy.

Although techniques for administering radiation therapy to the brain have improved considerably and the incidence of serious side effects has decreased significantly, radiation encephalopathy remains an important complication. *Acute radiation encephalopathy* is most likely to develop in young patients who have received large daily doses. Excessive radiation injures vessel endothelium, resulting in enhanced vascular permeability, cerebral edema, and numerous hemorrhages. The child may suddenly become irritable and lethargic, complain of headache, or present with focal neurologic signs and seizures. Patients occasionally develop hemiparesis due to an infarct secondary to vascular occlusion of the cerebral vessels. Steroids are often beneficial in reducing the cerebral edema and reversing the neurologic signs. *Late radiation encephalopathy* is characterized by headaches and slowly progressive focal neurologic signs, including hemiparesis and seizures. Some children with acute lymphatic leukemia treated with a combination of intrathecal methotrexate and cranial irradiation develop neurologic signs months or years later; signs consist of increasing lethargy, loss of cognitive abilities, dementia, and focal neurologic signs and seizures (see Chapter 486). The CT scan shows calcifications in the white matter, and the postmortem examination demonstrates a necrotizing encephalopathy. This devastating complication of the treatment of leukemia has prompted re-evaluation of the use of cranial radiation in the treatment of these children.

Zellweger Syndrome (Cerebrohepatorenal Syndrome [CHRS]).

This rare, lethal disorder is inherited as an autosomal recessive trait. It represents the prototype of a group of peroxisomal disorders that have overlapping symptoms, signs, and biochemical abnormalities (see Chapter 75.2). Infants with Zellweger syndrome have dysmorphic facies consisting of frontal bossing and a large anterior

fontanel. The occiput is flattened, and the external ears are abnormal. A high-arched palate, excessive skinfolds of the neck, severe hypotonia, and areflexia are usually evident. Examination of the eyes reveals searching nystagmoid movements, bilateral cataracts, and optic atrophy. Generalized seizures become evident early in life, associated with severe global developmental delay and a significant bilateral hearing loss. The cause of the severe neurologic abnormalities is related to an arrest of migrating neuroblasts during early development, resulting in cerebral pachygyria with neuronal heterotopia (see Chapter 585.7). Hepatomegaly is a prominent finding shortly after birth, often associated with a history of prolonged neonatal jaundice. Patients with Zellweger syndrome rarely survive beyond 1 yr of age.

Chapter 592 - Neurodegenerative Disorders of Childhood

Michael V. Johnston

Neurodegenerative disorders of childhood encompass a large number of heterogeneous diseases that result from specific genetic and biochemical defects, chronic viral infections, and a significant group of conditions of unknown cause. In the past, children with suspected neurodegenerative disorders were subjected to brain and rectal biopsies, but with the advent of modern neuroimaging techniques and specific biochemical molecular diagnostic tests, these invasive procedures are rarely necessary. Nevertheless, the most important component of the investigation continues to be a thorough history and physical examination. The hallmark of a neurodegenerative disease is progressive deterioration of neurologic function with loss of speech, vision, hearing, or locomotion, often associated with seizures, feeding difficulties, and impairment of intellect. The age of onset, rate of progression, and principal neurologic findings determine whether the disease is primarily affecting the white or gray matter. Upper motor neuron signs are prominent early in the former, and convulsions, intellectual, and visual impairment in the latter. A precise history confirms regression of developmental milestones, and the neurologic examination localizes the process within the nervous system. Although the outcome is usually fatal and current therapeutic attempts have been unsuccessful, it is important to make the correct diagnosis so that genetic counseling may be offered and prevention strategies can be implemented. Bone marrow transplantation and other forms of cell and gene therapies are also becoming useful for preventing the progression of disease in presymptomatic individuals. For all conditions in which the specific enzyme defect is known, prevention by prenatal diagnosis (chorionic villus sampling or amniocentesis) is possible. Carrier detection is also often possible by enzyme assay. Table 592–1 summarizes the heredity, biochemical defects, and specific diagnostic abnormality in the inherited neurodegenerative disorders. Additional age of onset-related categorization is noted in Table 592–2 .

The inherited neurodegenerative disorders include the sphingolipidoses, neuronal ceroid lipofuscinoses, adrenoleukodystrophy, and sialidosis. The sphingolipidoses are characterized by intracellular storage of a normal lipid component of the cell membrane that results from a defect in catabolism of the compound. The sphingolipidoses are subclassified into six categories: Niemann-Pick disease, Gaucher disease, GM_1 gangliosidosis, GM_2 gangliosidosis, Krabbe disease, and metachromatic leukodystrophy. Niemann-Pick disease and Gaucher disease are

discussed in Chapter 75.4 . The spinocerebellar degenerative diseases (Friedreich ataxia, ataxia-telangiectasia, olivopontocerebellar atrophy, and abetalipoproteinemia) and degenerative disorders of the basal ganglia (Huntington disease, dystonia musculorum deformans, Wilson disease, and Hallervorden-Spatz disease) are discussed in Chapter 590 . Finally, a miscellaneous group of degenerative diseases is discussed in this section, including multiple sclerosis, Pelizaeus-Merzbacher disease, Alexander disease, Canavan spongy degeneration, kinky hair disease, Rett syndrome, and subacute sclerosing panencephalitis.

592.1 Sphingolipidoses

GANGLIOSIDOSES

See also Chapter 75.4 .

Gangliosides are glycosphingolipids, normal constituents of the neuronal and synaptic membranes. The basic structure of GM_1 ganglioside consists of an oligosaccharide chain attached to a hydroxyl group of ceramide and sialic acid bound to galactose. The gangliosides are catabolized by sequential cleavage of the sugar molecules by specific exoglycosidases. Abnormalities in catabolism result in an accumulation of the ganglioside within the cell. Defects in ganglioside degradation can be classified into two groups: the GM_1 gangliosidoses and the GM_2 gangliosidoses.

GM_1 Gangliosidoses.

The three subtypes of GM_1 gangliosidoses are classified according to age at presentation: infantile (type 1), juvenile (type 2), and adult (type 3). The condition is inherited as an autosomal recessive trait and results from a marked

TABLE 592.1-1 -- **Heredity and Biochemical Defects in the Neurodegenerative Disorders**

Neurodegenerative Disorder	Mode of Inheritance	Biochemical Defect	Specimen for Analysis
Sphingolipidosis			
GM_1 gangliosidosis	AR	ß-Galactosidase	Serum, leukocytes, skin fibroblasts
GM_2 gangliosidosis			
Tay-Sachs disease	AR	Hexosaminidase A	Serum, leukocytes, skin fibroblasts
Sandhoff disease	AR	Hexosaminidase A and B	Serum, leukocytes, skin fibroblasts
Krabbe disease	AR	Galactocerebrosidase	Leukocytes and skin fibroblasts
Metachromatic leukodystrophy	AR	Arylsulfatase A	Leukocytes and skin fibroblasts
Neuronal Ceroid Lipofuscinoses	AR	Pamitoyl-protein thioesterase (PPT) Tripeptidyl peptidasel (TPP1)	EM of skin biopsy
Adrenoleukodystrophy	XLR	VLCFA oxidation	Plasma, skin fibroblasts
Sialidosis	AR	Neuraminidase	Skin fibroblasts

AR = autosomal recessive; EM = electron microscopy; XLR = X-linked recessive; VLCFA = very long chain fatty acid.

TABLE 592.1-2 -- **Select "Intrinsic" Conditions Associated with Developmental Regression**

Age at Onset (yr)	Condition	Comments
<2—with hepatomegaly (see Chapter 76.3)	Fructose intolerance Galactosemia Glycogenosis (glycogen storage disease) types I–IV Mucopolysaccharidosis types I and II Niemann-Pick disease, infantile type Tay-Sachs disease Zellweger (cerebrohepatorenal) syndrome Gaucher disease type II	Vomiting, hypoglycemia, poor feeding, failure to thrive (when given fructose) Lethargy, hypotonia, icterus, cataract, hypoglycemia (when given lactose) Hypoglycemia, cardiomegaly (II) Coarse facies, stiff joints Gray matter disease, failure to thrive Seizures, cherry red macula, edema, coarse facies Hypotonia, high forehead, flat facies Extensor posturing, irritability

<2—without hepatomegaly	Krabbe disease Rett syndrome Maple syrup urine disease Phenylketonuria Menkes kinky hair disease Subacute necrotizing encephalopathy of Leigh Cerebro-oculofacioskeletal syndrome (of Pena and Shokeir) Canavan disease Pelizaeus-Merzbacher disease	Irritability, extensor posturing, optic atrophy and blindness Girls with deceleration of head growth, loss of hand skills, hand wringing, impaired language skills, gait apraxia Poor feeding, tremors, myoclonus, opisthotonos Light pigmentation, eczema, seizures Hypertonia, irritability, seizures, abnormal hair White matter disease Reduced white matter, failure to thrive White matter disease White matter disease
2–5	Niemann-Pick disease types III and IV Wilson disease Gangliosidosis type II Ceroid lipofuscinosis Mitochondrial encephalopathies (e.g., myoclonic epilepsy, ragged-red fibers [MERRF]) Ataxia-telangiectasia Huntington's disease (chorea) Hallervorden-Spatz syndrome Metachromatic leukodystrophy Adrenoleukodystrophy Subacute sclerosing panencephalitis	Hepatosplenomegaly, gait difficulty Liver disease, Kayser-Fleischer ring, deterioration of cognition is late Gray matter disease Gray matter disease Gray matter diseases Basal ganglia disease Basal ganglia disease Basal ganglia disease White matter disease White matter disease, behavior problems, falling school performance, quadriparesis Diffuse encephalopathy, myoclonus, may occur years after measles
5–15	Adrenoleukodystrophy Multiple sclerosis Neuronal ceroid lipofuscinosis, juvenile and adult (Spielmeyer-Vogt and Kuf disease) Schilder disease Refsum disease Sialidosis II, juvenile form	See above for adrenoleukodystrophy White matter disease Gray matter disease White matter disease, focal neurologic symptoms Peripheral neuropathy, ataxia, retinitis pigmentosa Cherry red macula, myoclonus, ataxia, coarse facies

From Liptak G: In Kliegman R (editor): Practical Strategies in Pediatric Diagnosis andTherapy. Philadelphia, WB Saunders, 1996, p 503.

deficiency of acid ß-galactosidase. This enzyme may be assayed in leukocytes and cultured fibroblasts. The acid ß-galactosidase gene has been mapped to chromosome 3p14.2. Prenatal diagnosis is possible by measurement of acid ß-galactosidase in cultured amniotic cells.

Infantile GM_1 gangliosidosis presents at birth or during the neonatal period with anorexia, poor sucking, and inadequate weight gain. Development is globally retarded, and generalized seizures are prominent. The phenotype is striking and shares many characteristics with Hurler syndrome. The facial features are coarse, the forehead is prominent, the nasal bridge is depressed, the tongue is large (macroglossia), and the gums are hypertrophied. Hepatosplenomegaly is present early in the course as a result of accumulation of foamy histiocytes, and kyphoscoliosis is evident because of anterior beaking of the vertebral bodies. The neurologic examination is dominated by apathy, progressive blindness, deafness, spastic quadriplegia, and decerebrate rigidity. A cherry red spot in the macular region is visualized in approximately 50% of cases. The **cherry red spot** is characterized by an opaque ring (sphingolipid-laden retinal ganglion cells) encircling the normal red fovea (Fig. 592–1). Children rarely survive beyond age 2–3 yr, and death is due to aspiration pneumonia.

Juvenile GM_1 gangliosidosis has a delayed onset beginning about 1 yr of age. The initial symptoms consist of incoordination, weakness, ataxia, and regression of language. Thereafter, convulsions, spasticity, decerebrate rigidity, and blindness are the major findings. Unlike the infantile type, this type is not usually marked by coarse facial features and hepatosplenomegaly. Radiographic examination of the lumbar vertebrae may show minor beaking. Children rarely survive beyond 10 yr of age. *Adult GM_1 gangliosidosis* is a slowly progressive disease consisting of spasticity, ataxia, dysarthria, and a gradual loss of cognitive function.

GM_2 Gangliosidoses.

The GM_2 gangliosidoses are a heterogeneous group of autosomal recessive inherited disorders that consist of several subtypes, including Tay-Sachs disease (TSD), Sandhoff disease, juvenile GM_2 gangliosidosis, and adult GM_2 gangliosidosis. *Tay-Sachs disease* is most prevalent in the Ashkenazi Jewish population and has a carrier rate of approximately 1/30. TSD is due to mutations in the HEXA gene located on chromosome 15q23-q24. Affected infants appear normal until approximately 6 mo of age, except for a marked startle reaction to noise that is evident soon after birth. Affected children then begin to lag in developmental milestones, and by 1 yr of age they lose the ability to stand, sit, and vocalize. Early hypotonia develops into progressive spasticity, and relentless deterioration follows, with convulsions, blindness, deafness, and cherry red spots in almost all patients (see Fig. 592–1). Macrocephaly becomes apparent by 1 yr of age and results from the 200-to 300-fold normal content of GM_2 ganglioside deposited within the brain. Few children live beyond 3–4 yr of age, and death is usually associated with aspiration or bronchopneumonia. A deficiency of the isoenzyme hexosaminidase A is found in tissues of patients with TSD. Mass screening for prenatal diagnosis of TSD is a reliable and cost-effective method of prevention because the

Figure 592.1-1 A cherry red spot in a patient with GM_1 gangliosidosis. Note the whitish ring of sphingolipid-laden ganglion cells surrounding the fovea.

condition occurs in a defined population (Ashkenazi Jews). An accurate and inexpensive carrier detection test is available (serum or leukocyte hexosaminidase A), and the disease can be reliably diagnosed by chorionic villus sampling during the 1st trimester of pregnancy in couples at risk (heterozygote parents).

Sandhoff disease is very similar to TSD in the mode of presentation, including progressive loss of motor and language milestones beginning at 6 mo of age. Seizures, cherry red spots, macrocephaly, and doll-like facies are present in most patients; however, children with Sandhoff disease may also have splenomegaly. The visual-evoked potentials (VEPs) are normal early in the course of Sandhoff disease and TSD but become abnormal or absent as the disease progresses. The auditory brainstem responses (ABRs) show prolonged latencies. The diagnosis of Sandhoff disease is established by finding deficient levels of hexosaminidase A and B in serum and leukocytes. Children usually die by 3 yr of age. Sandhoff disease is due to mutations in the HEXB gene located on chromosome 5q13.

Juvenile GM_2 gangliosidosis develops in midchildhood, initially with clumsiness followed by ataxia. Signs of spasticity, athetosis, loss of language, and seizures gradually develop. Progressive visual loss is associated with optic atrophy, but cherry red spots rarely occur in juvenile GM_2 gangliosidosis. A deficiency of hexosaminidase is variable (total deficiency to near normal) in these patients. Death occurs around 15 yr of age.

Adult GM_2 gangliosidosis is characterized by a myriad of neurologic signs, including slowly progressive gait ataxia, spasticity, dystonia, proximal muscle atrophy, and dysarthria. Generally, visual acuity and intellectual function are unimpaired. Hexosaminidase A or A and B activity is reduced significantly in the serum and leukocytes.

Krabbe Disease (Globoid Cell Leukodystrophy).

Krabbe disease (KD) is a rare autosomal recessive neurodegenerative disorder characterized by severe myelin loss and the presence of globoid bodies in the white matter. The gene for KD (GALC) is located on chromosome 14q24.3-q32.1. The disease results from a marked deficiency of the lysosomal enzyme galactocerebroside ß-galactosidase, which cleaves a galactose moiety from the ceramide portion of galactocerebroside. KD is a disorder of myelin destruction rather than abnormal myelin formation. Normally, myelination begins during the 3rd trimester, corresponding with a rapid increase of galactocerebroside ß-galactosidase activity in the brain. In patients with KD, galactocerebroside cannot be metabolized during the normal turnover of myelin because of deficiency of galactocerebroside ß-galactosidase. When galactocerebroside is injected into the brains of experimental animals, a globoid cell reaction ensues. It has been postulated that a similar phenomenon occurs in humans; nonmetabolized galactocerebroside stimulates the formation of globoid cells that reflect the destruction of oligodendroglial cells. Because oligodendroglial cells are responsible for the elaboration of myelin, their loss results in myelin breakdown, thus producing additional galactocerebroside and causing a vicious circle of myelin destruction.

The symptoms of KD become evident during the first few months of life and include excessive irritability and crying, unexplained episodes of hyperpyrexia, feeding problems, vomiting, and failure to thrive. During the initial stage of KD. children are often treated for colic or “milk allergy” with frequent formula changes. Generalized seizures may appear early in the course of the disease. Alterations in body tone with rigidity and opisthotonos and visual inattentiveness due to optic atrophy become apparent as the disease progresses. During the later stages of the illness, blindness, deafness, absent deep tendon reflexes, and decerebrate rigidity constitute the major physical findings. A nonenhanced CT scan of the head may show symmetric increased densities in the caudate nuclei and thalami. Most patients die by 2 yr of age.

Late-onset KD has been described beginning in childhood or during adolescence. Patients present with optic atrophy and cortical blindness, and their condition is often confused with the adrenoleukodystrophies. Slowly progressive gait disturbances, including spasticity and ataxia, are prominent. As with classic KD, globoid cells are abundant in the white matter, and leukocytes are deficient in galactocerebroside ß-galactosidase. An examination of the cerebrospinal fluid (CSF) shows an elevated protein content, and the nerve conduction velocities are markedly delayed due to segmental demyelination of the peripheral nerves. The VEPs decrease gradually in amplitude with no response in the late stages of the disease, and the ABRs are characterized by the presence of only waves I and II. CT scans and MRI studies highlight the marked decrease in white matter, especially of the cerebellum and centrum semiovale, with sparing of the subcortical u fibers. Prenatal diagnosis is possible by the assay of galactocerebroside ß-galactosidase activity in chorionic villi or in cultured amniotic fluid cells.

Metachromatic Leukodystrophy (MLD).

This disorder of myelin metabolism is inherited as an autosomal recessive trait and is characterized by a deficiency of arylsulfatase A activity. Several mutations in the gene encoding for arylsulfatase A have been identified. The gene is located on chromosome 22q13-13qter, and DNA diagnosis is possible. The absence or deficiency of arylsulfatase A leads to accumulation of cerebroside sulfate within the myelin sheath of the central nervous system (CNS) and peripheral nervous system due to the inability to cleave sulfate from galactosyl-3-sulfate ceramide. The excessive cerebroside sulfate is thought to cause myelin breakdown and destruction of oligodendroglia. Prenatal diagnosis of MLD is made by assay of arylsulfatase A in chorionic villi or cultured amniotic fluid cells. Cresyl violet applied to tissue specimens produces metachromatic staining of the sulfatide granules, giving the disease its name. Six disorders are included in the MLD group of diseases, classified by the age at onset and enzyme deficiency. Three conditions are briefly discussed: the classic or late infantile, juvenile, and adult leukodystrophies.

Late infantile MLD begins with insidious onset of gait disturbances between 1 and 2 yr of age. The child initially appears awkward and frequently falls, but locomotion is

impaired significantly and support is required in order to walk. The extremities are hypotonic, and the deep tendon reflexes are absent or diminished. Within the next several months, the child can no longer stand, and deterioration in intellectual function becomes apparent. The speech is slurred and dysarthric, and the child appears dull and apathetic. Visual fixation is diminished, nystagmus is present, and examination of the retina shows optic atrophy. Within 1 yr from the onset of the disease, the child is unable to sit unsupported, and progressive decorticate postures develop. Feeding and swallowing are impaired due to pseudobulbar palsies, and a feeding gastrostomy is required. Patients ultimately become stuporous and die of aspiration or bronchopneumonia by age 5–6 yr. Neurophysiologic evaluation shows progressive changes in the VEPs, ABRs, and somatosensory-evoked potentials (SSEPs), and the nerve conduction velocities (NCVs) of the peripheral nerves are significantly reduced. CT and MRI images of the brain indicate diffuse symmetric attenuation of the cerebellar and cerebral white matter, and examination of the CSF shows an elevated protein content. Bone marrow transplantation is a promising experimental therapy for the management of late infantile MLD. Favorable outcomes have been reported only in patients treated very early in the course of the disease. The total number of patients treated is relatively small and the follow-up too short to draw conclusions about the efficacy of bone marrow transplantation.

Juvenile MLD has many features in common with late infantile MLD, but the onset of symptoms is delayed to 5–10 yr of age. Deterioration in school performance and alterations in personality may herald the onset of the disease. This is followed by incoordination of gait, urinary incontinence, and dysarthria. Muscle tone becomes increased, and ataxia, dystonia, or tremor may be present. During the terminal stages, generalized tonic-clonic convulsions are prominent and are difficult to control. Patients rarely live beyond midadolescence.

Adult MLD occurs from the 2nd to 6th decade. Abnormalities in memory, psychiatric disturbances, and personality changes are prominent features. Slowly progressive neurologic signs, including spasticity, dystonia, optic atrophy, and generalized convulsions, lead eventually to a bedridden state characterized by decorticate postures and unresponsiveness.

592.2 Neuronal Ceroid Lipofuscinoses

Neuronal ceroid lipofuscinoses constitutes the most common class of neurodegenerative diseases in children and consist of three disorders inherited as autosomal recessive traits. They are autosomal recessive disorders characterized by the storage of an autofluorescent substance within lysosomes of neurons and other tissues. Eight genes have been identified. In the infantile forms and some early childhood forms, mutations have been identified in the lysosomal enzyme palmitoyl-protein thioesterase-1 (PPT).

Infantile type (Haltia-Santavuori) begins near the end of the 1st year of life with myoclonic seizures, intellectual deterioration, and blindness. Optic atrophy and brownish discoloration of the macula are evident on examination of the retina, and cerebellar ataxia is prominent. The electroretinogram (ERG) typically shows small-amplitude or absent waveforms. Death occurs at approximately 10 yr of age. The gene defect causing the infantile form has been assigned to chromosome 1p32. *Late infantile type (Jansky-Bielschowsky)* is the most common type of neuronal ceroid lipofuscinosis. The presenting manifestation is myoclonic seizures beginning between 2 and 4 yr of age in a previously normal child. Dementia and ataxia are combined with a progressive loss of visual acuity and microcephaly. Examination of the retina shows marked attenuation of vessels, peripheral black “bone spicule” pigmentary abnormalities, optic atrophy, and a subtle brown pigment in the macular region. The ERG is abnormal early in the course as a result of deposition of the abnormal storage substance within the rod and cone area of the retina. VEPs are characteristic and consist of markedly enlarged responses followed by absent waveforms with progression of the disease. The autofluorescent material is deposited in neurons, fibroblasts, and secretory cells. Electron microscopic examination of the storage material in skin or conjunctival biopsy material typically shows curvilinear bodies or “fingerprint profiles.”

Juvenile type (Spielmeyer-Vogt) is characterized by progressive visual loss and intellectual impairment beginning between 5 and 10 yr of age. The funduscopic changes are similar to those for the late infantile type. The ERG is also abnormal early in the course of the disease, but in the juvenile type the VEPs typically are characterized by small-amplitude waves and, later, absence of waveforms as the disease progresses. Myoclonic seizures are not as prominent as in the late infantile type of neuronal ceroid lipofuscinosis, but dystonic posturing is marked during the late stages of the disease. Elevated urine dolichol levels are a nonspecific finding. Ultrastructural abnormalities of skin biopsy samples are present in most cases. CLN2, which encodes the lysosomal enzyme tripeptidyl peptidase 1, and several others have been identified in juvenile forms.

592.3 Adrenoleukodystrophy

See Chapter 75.2 .

The adrenoleukodystrophies consist of a group of CNS degenerative disorders that are often associated with adrenal cortical insufficiency and are inherited by X-linked recessive transmission. *Classic adrenoleukodystrophy* (ALD) becomes symptomatic between 5 and 15 yr of age with evidence of academic deterioration, behavioral disturbances, and gait abnormalities. ALD is caused by mutations in the ABCD 1 gene located on Xq28, which encodes peroxisomal transporter involved in the import of very long chain fatty acids into the peroxisome. The incidence of ALD approximates 1/20,000 boys. Generalized seizures are common in the early stages. Upper motor neuron signs include spastic quadriparesis and contractures, ataxia, and marked swallowing disturbances secondary to pseudobulbar palsy. These dominate the terminal stages of the illness. Hypoadrenalism is present in approximately 50% of cases, and adrenal insufficiency characterized by abnormal skin pigmentation (tanning without exposure to sun) may precede the onset of neurologic symptoms. CT scans and MRI studies of patients indicate periventricular demyelination beginning posteriorly; this advances progressively to the anterior regions of the cerebral white matter. ABRs, VEPs, and SSEPs may be normal initially but ultimately show prolonged latencies and abnormal waveforms. Death supervenes within 10 yr of the onset of the neurologic signs; however, long-term follow-up has shown that bone marrow transplant can prevent the progress of the disease when done at an early stage.

Adrenomyeloneuropathy begins with a slowly progressive spastic paraparesis, urinary incontinence, and onset of impotence during the 3rd or 4th decade, even though adrenal insufficiency may have been present since childhood. Cases of typical ALD have occurred in families in whom the propositus presented with adrenomyeloneuropathy. One of the most difficult problems in the management of X-linked ALD is the common observation that affected individuals in the same family may have quite different clinical courses. For example, in one family, one affected boy had severe classic ALD culminating in death by age 10 yr; another affected male (a brother) had late-onset adrenomyeloneuropathy, and a third had no symptoms at all. Counseling families with presymptomatic males is extraordinarily difficult because there is no reliable method for predicting the clinical course.

Neonatal ALD is characterized by marked hypotonia, severe psychomotor retardation, and early onset of seizures. It is inherited as

an autosomal recessive condition. Visual inattention is secondary to optic atrophy. Results of adrenal function tests are normal, but adrenal atrophy is evident postmortem. Correction of adrenal insufficiency is ineffective in halting neurologic deterioration.

592.4 Sialidosis

Sialidosis is inherited as an autosomal recessive trait and results from accumulation of a sialic acid-oligosaccharide complex secondary to a deficiency in the lysosomal enzyme neuraminidase. The lysosomal sialidase gene has been mapped to chromosome 6p21.3. Urinary excretion of sialic acid–containing oligosaccharides is increased significantly in affected patients.

Sialidosis type I, the cherry red spot–myoclonus syndrome (CRSM), usually presents during the 2nd decade of life, when a patient complains of visual deterioration. Inspection of the retina shows a cherry red spot, but, unlike patients with TSD, visual acuity declines slowly in individuals with CRSM. Myoclonus of the extremities is gradually progressive and often debilitating and eventually renders patients nonambulatory. The myoclonus is triggered by voluntary movement, touch, and sound and is not controlled with anticonvulsants. Generalized convulsions responsive to antiepileptic drugs occur in most patients.

Sialidosis type II may be subdivided into infantile and juvenile forms, depending on the age at presentation. In addition to cherry red spots and myoclonus, these patients have somatic involvement, including coarse facial features, corneal clouding (rarely), and dysostosis multiplex, producing anterior beaking of the lumbar vertebrae. Examination of lymphocytes shows vacuoles in the cytoplasm, biopsy of the liver demonstrates cytoplasmic vacuoles in Kupffer cells, and membrane-bound vacuoles are found in Schwann cell cytoplasm, all attesting to the multiorgan nature of sialidosis type II. No distinctive neuroimaging findings or abnormalities in electrophysiologic studies are noted in this group of disorders. Patients with sialidosis have been reported to live beyond the 5th decade.

Some cases of what appears to be sialidosis type II are the result of combined deficiencies of ß-galactosidase and a-neuraminidase due to deficiency of a “protective protein” that prevents premature intracellular degradation of the two enzymes. Clinically, affected patients are indistinguishable from those with sialidosis type II, either the infantile or juvenile form, caused by isolated a-neuraminidase deficiency. The diagnosis may be missed if ß-galactosidase testing is done and testing of a-neuraminidase activity in fibroblasts is not completed.

592.5 Miscellaneous Disorders

Multiple Sclerosis.

Multiple sclerosis (MS) is a chronic, remitting disorder characterized by multiple white lesions in the CNS separated by time and location. The condition is rare in the pediatric population; onset before age 10 yr occurs in 0.2–2% of all cases. There is a greater incidence of MS in females in the pediatric age group compared with adults. The cause of MS is unknown, but interactive genetic, immunologic, and infectious factors are probably responsible. The most frequent presenting symptom is unilateral weakness or ataxia. Headache is an important early component of the disease and is often severe, prolonged, and generalized. Ill-defined paresthesias involving the lower extremities, distal portions of the hands and feet, and the face are common. Visual symptoms including diplopia, blurred vision, or sudden visual loss secondary to optic neuritis are also important early manifestations of MS. Vertigo, dysarthria, and sphincter disturbances are relatively uncommon. *Neuromyelitis optica (Devic disease)* is a variant of classic MS and consists of optic neuritis and transverse myelitis, which occur conjointly.

The *pathology* of MS consists of demyelination with the formation of plaques. No reliable laboratory test unequivocally confirms the diagnosis of MS, except for an autopsy. MRI is the neuroimaging technique of choice; small plaques of 3–4?mm can be identified, particularly those located in the brainstem and spinal cord (Fig. 592–2).

The *treatment* of MS is supportive, and particular attention is given to the management of a neurogenic bladder. No evidence shows that corticosteroids alter the long-term course of the disease, but they may expedite recovery after an acute attack. Studies indicate that interferon ß-1b given subcutaneously every other day or interferon ß-1a given intramuscularly every day on a weekly basis are effective in the treatment of MS by decreasing disease activity and disease burden, as shown by serial gadolinium-enhanced lesions in brain MRI scan in adults.

Figure 592.5-2 Multiple sclerosis. *A,* T2 weighted MRI scan of brain demonstrates multiple lesions located in the white matter characteristic of multiple sclerosis (*white arrow*). *B,* T1 weighted MRI scan of spine indicates a demyelinating plaque of multiple sclerosis in the midcervical region (*white arrow*).

The *prognosis* for childhood MS is similar to that in adults; recovery is often

complete, and progression of the disease tends to be slow, with long periods of remission in most cases. Promising immunologic therapy, including the use of intravenous immunoglobulins, is currently being investigated.

Pelizaeus-Merzbacher Disease.

This disease consists of a group of disorders that are characterized by nystagmus and abnormalities of myelin. The classic form is inherited as an X-linked recessive trait caused by abnormalities in the proteolipid protein (PLP) gene, which is essential for CNS myelin formation and oligodendrocyte differentiation. Mutations in the same gene can cause *familial spastic paraparesis.* It is recognized by nystagmus and roving eye movements with head nodding during infancy. The gene is located on chromosome Xq22. Molecular diagnosis of Pelizaeus-Merzbacher disease is possible using mutation analysis. However, as with most X-linked diseases, the molecular diagnosis of Pelizaeus-Merzbacher disease is complex because exonic mutations are present in only 10–25% of patients with the disease. A child's developmental milestones are delayed, and ataxia, choreoathetosis, and spasticity ultimately develop. Optic atrophy and dysarthria are associated findings, and death occurs in the 2nd or 3rd decade. The major pathologic finding is a loss of myelin with intact axons, suggesting a defect in the function of oligodendroglia. Studies point to a genetic defect in the biosynthesis of proteolipid apoprotein, a protein that is concerned with the differentiation and maintenance of oligodendrocytes. An MRI scan shows a symmetric pattern of delayed myelination. Multimodal-evoked potential studies demonstrate early in the course a pattern consisting of loss of waves III–V on the ABR. This finding is useful in the investigation of nystagmus in infant boys. VEPs show prolonged latencies, and SSEPs show absent cortical responses or delayed latencies.

Alexander Disease.

This is a rare disorder that occurs sporadically and causes progressive macrocephaly during the 1st year of life. It is caused by mutations in the glial fibrillary acidic protein (GFAP) gene. Pathologic examination of the brain discloses deposition of eosinophilic hyaline bodies in a perivascular distribution throughout the brain and beneath the pia mater. Degeneration of white matter is most prominent in the frontal lobes, and a CT scan during this stage shows corresponding attenuation of the cerebral white matter. Affected children develop progressive loss of intellect, spasticity, and unresponsive seizures causing death by 5 yr of age.

Canavan Spongy Degeneration.

See Chapter 74.14 .

Menkes Disease.

Menkes disease (kinky hair disease) is a progressive neurodegenerative condition inherited as a sex-linked recessive trait. The Menkes gene codes for a copper transporting P-type ATPase, and mutations in the protein are associated with low serum copper and ceruloplasmin levels as well as a defect in copper absorption and transport across the intestines. Symptoms begin during the first few months of life and include hypothermia, hypotonia, and generalized myoclonic seizures. The facies are distinctive, with chubby, rosy cheeks and kinky, colorless, friable hair. Microscopic examination of the hair shows several abnormalities, including trichorrhexis nodosa (fractures along the hair shaft) and pili torti (twisted hair). Feeding difficulties are prominent and lead to failure to thrive. Severe mental retardation and optic atrophy are constant features of the disease. Neuropathologic changes include tortuous degeneration of the gray matter and marked changes in the cerebellum with loss of the internal granule cell layer and necrosis of the Purkinje cells. Death occurs by 3 yr of age in untreated patients.

Copper-histidine therapy has been shown to be effective in preventing neurologic deterioration in some patients with Menkes' disease, particularly when treatment is begun during the neonatal period or, preferably, with the fetus. Copper is essential during the early stages of CNS development, and its absence probably accounts for the neuropathologic changes. Copper-histidine is given subcutaneously in a dose of 50–150?µg elemental copper/kg/24?hr for the duration of the child's life. The serum copper and ceruloplasmin levels return to the normal range within 2–3 wk of commencing therapy.

The *occipital horn syndrome*, a skeletal dysplasia caused by different mutations in the same gene as that involved in Menkes disease, is a relatively mild disease. The two diseases are often confused, because the biochemical abnormalities are identical. Resolution of the uncertainty about treatment of patients with Menkes disease will require careful genotype-phenotype correlation, along with further clinical trials of copper therapy.

Rett Syndrome.

Rett syndrome (RS) is a disorder of developmental regression and deceleration of brain growth over the first year of life after a relatively normal neonatal course occurring predominantly in girls. The frequency is approximately 1/15,000 to 1/22,000. RS is caused by mutations in MeCP2, a transcription factor that binds to methylated CpG islands and silences transcription. Development proceeds normally until 1 yr of age, when regression of language and motor milestones and acquired microcephaly become apparent. An ataxic gait or fine tremor of hand movements is an early neurologic finding. Most children develop peculiar sighing respirations with intermittent periods of apnea that may be associated with cyanosis. The hallmark of Rett syndrome is repetitive hand-wringing movements and a loss of purposeful and spontaneous use of the hands; these may not appear until 2–3 yr of age. Autistic behavior is a typical finding in all patients. Generalized tonic-clonic convulsions occur in the majority and are usually well controlled by anticonvulsants. Feeding disorders and poor weight gain are common. After the initial period of neurologic regression, the disease process appears to plateau, with persistence of the autistic behavior. Death occurs during adolescence or during the 3rd decade. Cardiac arrhythmias may result in sudden, unexpected death.

Postmortem studies show significantly reduced brain weight (60–80% of normal) with a decrease in the number of synapses, associated with a decrease in dendritic length and branching. The phenotype may be related to failure to suppress expression of genes that normally are silent during the early phases of postnatal development. Although very few males survive with the classic RS phenotype, genotyping of boys without the classic RS phenotype but with mental retardation and other atypical neurologic features has detected a significant number with mutations

in MeCP2. Some data indicate that mutations in MeCP2 may be as common in mentally retarded populations as fragile X syndrome. This suggests that mutations in the Rett gene may cause a far broader spectrum of neurodevelopmental disability than once thought.

Subacute Sclerosing Panencephalitis.

This is a rare, progressive, slow-virus infection of the CNS caused by a measles-like virus (Chapter 225.1). The number of reported cases has decreased dramatically to 0.06 cases/million population, paralleling the decline in reported measles cases. The initial clinical manifestations include personality changes, aggressive behavior, and impaired cognitive function. Myoclonic seizures soon dominate the clinical picture. Later, generalized tonic-clonic convulsions, hypertonia, and choreoathetosis become evident, followed by progressive bulbar palsy, hyperthermia, and decerebrate postures. Funduscopic examination early in the course of the disease reveals papilledema in approximately 20% of the cases. Optic atrophy, chorioretinitis, and macular pigmentation are observed in most patients. The *diagnosis* is established by the typical clinical course and one of the following: (1) measles antibody detected in the CSF, (2) a characteristic electroencephalogram consisting of bursts of high-voltage slow waves interspersed with a normal background in the early stages, and (3) typical histologic findings

---

in the brain biopsy or postmortem specimen. *Treatment* with a series of antiviral agents has been attempted without success. Death occurs usually within 1–2 yr from the onset of symptoms. **REFERENCES**

Chapter 593 - Acute Stroke Syndromes

Michael V. Johnston

Hemiplegia secondary to vascular disorders occurs in children with an incidence of 1–3/100,000 per year. The pediatric causes of stroke are distinctive compared with adult causes. Types of stroke include arterial and venous thrombosis, intracranial hemorrhage, arterial embolism, and various miscellaneous conditions. The cause of stroke in children is established in approximately 75% of cases (Box 593–1). Because the mode of presentation of acute stroke syndromes is not uniform, a brief description of the most prevalent forms of pediatric stroke follows.

593.1 Arterial Thrombosis/Embolism

Arterial thrombosis and embolism may involve major cerebral arteries (internal carotid or anterior, middle, and posterior cerebral artery occlusion) or smaller cerebral arteries. Certain thrombotic processes affect large vessels and others more commonly involve small arteries. *Thrombosis of the internal carotid artery* may result from blunt trauma to the posterior pharynx caused by a fall on a pencil or popsicle stick in the child's mouth. The injury produces a tear in the intima of the vessel wall, which may lead to formation of a dissecting aneurysm. Cerebral symptoms result from shedding of emboli from the thrombus. The onset of symptoms may be delayed for up to 24?hr after the accident, with a stuttering but progressive flaccid hemiplegia, lethargy, and aphasia if the dominant hemisphere is involved. Focal motor seizures are a common complication. Dissection of vessels in the vertebral basilar circulation can lead to acute signs of brainstem dysfunction.

A *retropharyngeal abscess* may produce an identical clinical picture, but in this case the arterial thrombosis results from inflammation of the intima. A cerebral angiogram or MRI/magnetic resonance angiography (MRA) typically demonstrates occlusion of the internal carotid artery, and a CT/MRI scan shows a hypodense lesion outlining the area of infarction.

Embolization of cerebral vessels may also produce acute hemiparesis. Cardiac abnormalities are the most common overall cause of thromboembolic stroke in children. Cardiac causes include arrhythmias (particularly atrial fibrillation), myxoma, paradoxical emboli through a patent foramen ovale, and bacterial endocarditis that results in a mycotic aneurysm. Air emboli may complicate surgery, and fat emboli occur with fracture of long bones. Septic emboli may seed the cerebral vessels and

evolve into an area of cerebritis leading to a cerebral abscess.

Cyanotic congenital heart disease in children younger than 2 yr may cause thrombosis, particularly of the middle cerebral artery. These patients are particularly vulnerable when the oxygen saturation is significantly decreased together with a viral illness or dehydration. Cardiac procedures, including catheterization and complex cardiac surgery operations (e.g., Fontan), can result in arterial thrombosis from embolization of a clot. If a cardiac cause of arterial thrombosis is suspected, the child must have an echocardiogram as part of the investigation.

Occlusive vascular disorders are also important causes of acute hemiplegia in the pediatric population. *Basal arterial occlusion with telangiectasia* or *moyamoya ("puff of smoke") disease* has a characteristic angiogram (Fig. 593–1). The condition is more common in girls and often presents with headache and bilateral upper motor neuron signs. It may also present with chorea. Intermittent episodes of transient ischemic attacks can produce progressive neurologic signs and severe disability. Surgical procedures designed to enhance cerebral flow (superficial temporal artery to middle cerebral artery shunt and laying the superficial temporal artery on the arachnoid membrane) have variable results.

Sickle cell disease is the most common cause of stroke in black children and is associated with large vessel stenosis of the proximal middle cerebral or distal internal carotid arteries.

Coagulation disorders are an important risk factor for stroke in children and neonates. Mutations in factor V Leiden and prothrombin, deficiencies in protein C, protein S, and antithrombin III, as well as antiphospholipid antibodies, have been identified in up to 50% of infants and children with cerebral thromboembolism (see Chapters 470 and 471). *Occlusion of small arteries* is also associated with diabetes mellitus,

neurofibromatosis, postvaricella angiopathy, head and neck radiation, oral contraceptives, and illicit drug use (amphetamines, cocaine). Patients present with unilateral neurologic signs, and recovery is often complete because of the small area of infarction. Patients with *thrombosis of small arteries*, including the perforating striate vessels, which result from polyarteritis nodosa and homocystinuria, generally have a progressive debilitating course characterized by bilateral signs and high mortality rate.

593.2 Venous Thrombosis

Venous sinus thrombosis may be subdivided into septic and nonseptic causes. The symptoms and signs may evolve over days and in neonates are characterized by diffuse neurologic signs and seizures, whereas focal neurologic signs are more prominent in children. Dilated scalp veins, a bulging anterior fontanel, and symptoms and signs of increased intracranial pressure may be present.

Septic causes of venous sinus thrombosis include encephalitis and bacterial meningitis. Hemiplegia is a relatively common complication of **bacterial meningitis** caused by thrombosis of the superficial cortical and deep penetrating veins. Additional infectious causes of septic sinus thrombosis in children include **otitis media** and **mastoiditis** with involvement of the dural vessels, as well as retrograde orbital infections producing **cavernous sinus thrombosis**.

Aseptic causes include **severe dehydration** in infancy, which may cause thrombosis of the superior sagittal sinus and the superficial cortical veins that result from hyperviscosity and sludging of blood. Conditions resulting in hypercoagulopathy, cyanotic congenital heart diseases, and leukemic infiltrates of cerebral veins are additional causes of nonseptic acute hemiplegia of childhood. Prothrombotic disorders including deficiencies of inhibitors of coagulation such as protein C, protein S, antithrombin III, mutations in Leiden factor V, and anticardiolipin antibodies are found in 12–50% of cases (see Chapters 470 and 471).

593.3 Intracranial Hemorrhage

Intracranial hemorrhage may occur in the subarachnoid space, or the bleeding may be primarily located in the parenchyma of the brain. Subarachnoid bleeding is characterized by severe headache, nuchal rigidity, and progressive loss of consciousness, and intracerebral bleeding is characterized by focal neurologic signs and seizures. Intracranial hemorrhage is a common event in premature infants and is discussed in Chapter 88.2 .

Arteriovenous malformations result from failure of normal capillary bed development between arteries and veins during

Figure 593.3-1 Cerebral angiogram showing idiopathic supraclinoid-internal carotid arteriopathy with classic moyamoya collaterals (*arrow*).

embryogenesis. Arteriovenous malformations produce abnormal shunting of blood, causing an expansion of vessels and a space-occupying effect or rupture of a vein and intracerebral bleeding. Arteriovenous malformations are typically located in the cerebral hemisphere, but they may be situated in the cerebellum, brainstem, or spinal cord. Although the malformation may remain asymptomatic throughout life, rupture and bleeding can occur at any age. Children with arteriovenous malformations frequently have a history of seizures and migraine-like headaches. Typical migraine alternates from one side of the head to the other, whereas headaches associated with an arteriovenous malformation classically remain on the same side. Auscultation of the skull is positive for a high-pitched bruit in approximately 50% of cases. Rupture of an arteriovenous malformation causes a severe headache, vomiting, nuchal rigidity caused by subarachnoid bleeding, progressive hemiparesis, and a focal or generalized seizure. Cavernous angiomas may be familial and are of lower risk for spontaneous hemorrhage. An **arteriovenous malformation of the vein of Galen** during infancy can cause high-output congestive heart failure secondary to shunting of large volumes of blood or progressive hydrocephalus and increased intracranial pressure secondary to obstruction of the cerebrospinal fluid (CSF) pathways. Vein of Galen malformations are difficult to treat and are associated with a poor prognosis.

Cerebral aneurysms producing symptoms in children are relatively rare. In contrast to those in adults, aneurysms in children tend to be large and are located at the carotid bifurcation or on the anterior and posterior cerebral arteries rather than the

circle of Willis. The aneurysmal dilatation results from a congenital weakness of the vessel, and in some cases a deficiency of type III collagen has been demonstrated. In children, there is an association between cerebral aneurysms and coarctation of the aorta and bilateral polycystic kidney disease. Although most ruptured aneurysms bleed into the subarachnoid space, causing an intense headache, nuchal rigidity, and coma, intracerebral hemorrhage and progressive hemiparesis also occur. Additional causes of intracerebral hematoma include hematologic disorders, particularly thrombocytopenic purpura and hemophilia. Finally, trauma can produce hemiparesis due to intracerebral bleeding or a subdural or epidural hematoma. A contrast CT scan or MRI with gadolinium and MRA is useful for identifying large arteriovenous malformations; however, four-vessel cerebral angiography is the study of choice for investigating arteriovenous malformations and cerebral aneurysm.

593.4 Differential Diagnosis of Strokelike Events

Etiology and Clinical Manifestations.

Alternating hemiplegia of childhood is occasionally associated with migraine, but in most cases the cause is unknown. It develops in infants between 2 and 18 mo of age and is characterized by intermittent episodes of hemiplegia alternating from one side of the body to the other. Rarely, both sides are involved during an attack. Choreoathetosis and dystonic movements are commonly observed in the hemiparetic extremity. Signs spontaneously regress with sleep but recur with awakening. The hemiplegia persists for minutes to weeks and then resolves spontaneously. The condition has a poor prognosis with progressive mental retardation and developmental disabilities. Results of neuroimaging and metabolic studies are negative.

Several **metabolic diseases** are associated with strokelike episodes in children, including mitochondrial encephalomyelopathy (MELAS; see Chapter 591.2), ornithine transcarbamylase deficiency, pyruvate dehydrogenase deficiency, and homocystinuria.

Todd paralysis may be confused initially with a stroke. The hemiparesis follows a focal seizure, but the weakness and neurologic signs disappear completely within 24?hr of the convulsion. Although the cause of Todd paralysis remains unknown, the hemiparesis probably results from an inhibitory phenomenon, possibly related to neurotransmitter dysfunction.

Additional causes of hemiparesis include *cerebral tumor, encephalitis* (particularly herpes), *focal postviral encephalitis*, and *status epilepticus*. In some pediatric series of unexplained stroke, *lipid abnormalities*, including elevated triglycerides and low levels of high-density lipoprotein cholesterol, have been found in approximately 20% of the cases. The family histories of these children reveal an increased incidence of premature coronary heart disease and early ischemic cerebrovascular diseases. Screening of at-risk families identifies children who may benefit from long-term dietary management.

Diagnosis.

The most critical component of the investigation is a thorough history and physical examination, searching for an underlying disease process; evidence of trauma; an infectious, metabolic, or hematologic disorder; neurocutaneous syndrome; increased intracranial pressure; or hydrocephalus. Appropriate tests for infectious diseases, metabolic disorders, and hematologic disorders are based on the results of the

history and physical examination. An electroencephalogram (EEG) may be helpful in localizing the disease process but rarely establishes the diagnosis. A brain scan is extremely useful in cases of focal encephalitis, cerebritis, cerebral abscess, and infarction. A CT scan can detect recent bleeding or a large area of infarction, but diffusion weighted MRI and MRA are superior for early detection of cerebral ischemia and assessment of cerebral vessels. A cerebral angiogram may be useful in some cases in which MRI studies are nondiagnostic, such as to detect vasculitis or sites of intracranial hemorrhage. In these cases, a four-vessel cerebral angiogram is indicated. Electrocardiography and echocardiography may help to exclude intrinsic cardiac diseases or an arrhythmia as a cause of the stroke. Finally, the basic investigations for a child with an unexplained stroke syndrome should be organized to eliminate the following conditions: (1) vasculitis and connective tissue diseases (ESR, C3, C4, RF, ANA), (2) lipid disorders, (3) coagulation disorders, (4) hematologic disorders (sickle cell disease, thrombocytopenia), (5) metabolic disorders

(homocystinuria, Fabry disease, MELAS), and (6) an infectious etiology (meningitis and encephalitis).

Treatment.

Specific therapies include low molecular weight heparin for venous sinus thrombosis and prevention of recurrent cardiac emboli. Thrombolytic therapies (e.g., tissue plasminogen activator) are useful within 3?hr after stokes in adults but have not been studied in children. The contraindications for the use of an antithrombotic agent include significant intracerebral hemorrhage and hypertension. Regular blood transfusions reduce the incidence of stroke in sickle cell disease. Immunosuppressant therapy for vasculitis and surgical evacuation of a large blood clot are other examples of specific therapies. Rehabilitation requirements after a stroke can include speech therapy, occupational and physical therapy, psychologic services, and special education. These treatment regimens are most effectively provided in a multidisciplinary setting.

Chapter 594 - Central Nervous System Infections

Charles G. Prober

Acute infection of the central nervous system (CNS) is the most common cause of fever associated with signs and symptoms of CNS disease in children. Infection may be caused by virtually any microbe, the specific pathogen being influenced by the age and immune status of the host and the epidemiology of the pathogen. In general, viral infections of the CNS are much more common than bacterial infections, which, in turn, are more common than fungal and parasitic infections. Infections caused by rickettsiae (e.g., Rocky Mountain spotted fever and *Ehrlichia*) are relatively uncommon but assume important roles under certain epidemiologic circumstances. *Mycoplasma* spp also can cause infections of the CNS, although their precise contribution often is difficult to determine.

Regardless of etiology, most patients with acute CNS infection have similar clinical syndromes. Common symptoms include headache, nausea, vomiting, anorexia, restlessness, and irritability; however, most of these symptoms are nonspecific. Common signs of CNS infection, in addition to fever, include photophobia, neck pain and rigidity, obtundation, stupor, coma, seizures, and focal neurologic deficits. The severity and constellation of signs are determined by the specific pathogen, the host, and the area of the CNS affected. Infection of the CNS may be diffuse or focal. Meningitis and encephalitis are examples of diffuse infection. Meningitis implies primary involvement of the meninges, whereas encephalitis indicates brain parenchymal involvement. Because these anatomic boundaries are often not distinct, many patients have evidence of both meningeal and parenchymal involvement and should be considered to have meningoencephalitis. Brain abscess is the best example of a focal infection of the CNS. The neurologic expression of this infection is determined by the site and extent of the abscess(es).

The diagnosis of diffuse CNS infections depends on careful examination of cerebrospinal fluid (CSF) obtained by lumbar puncture (LP). Table 594–1 (Table Not Available) provides an overview of the expected CSF abnormalities with various CNS disorders.

594.1 Acute Bacterial Meningitis Beyond the Neonatal Period

Bacterial meningitis is one of the most potentially serious infections occurring in infants and older children. This infection is associated with a high rate of acute complications and risk of long-term morbidity. The etiology of bacterial meningitis and its treatment during the neonatal period (0–28 days) are generally distinct from those in older infants and children (Chapter 98). Nonetheless, the etiology of meningitis in the neonatal and postneonatal periods may overlap, especially in 1–2 mo old patients, in whom group B *Streptococcus, Streptococcus pneumoniae* (pneumococcus), *Neisseria meningitidis* (meningococcus), and *Haemophilus influenzae* type b all may cause meningitis.

The incidence of bacterial meningitis is sufficiently high in febrile infants that it should be included in the differential diagnosis of altered mental status or other neurologic dysfunction.

Etiology.

During the first 2 mo of life, the bacteria that cause meningitis in normal infants reflect the maternal flora and the environment to which the infant is exposed. The most common pathogens include groups B and D streptococci, gram-negative enteric bacilli, and *Listeria monocytogenes*. In addition, meningitis in this age group may occasionally be due to *H. influenzae* (both type b and nonencapsulated strains) and the other pathogens more typically found in older patients.

Bacterial meningitis in children 2 mo–12 yr of age is usually caused by *S. pneumoniae, N. meningitidis,* or *H. influenzae* type b. Before the widespread use of *H. influenzae* type b vaccines, approximately 70% of cases of bacterial meningitis among children younger than 5 yr were due to *H. influenzae* type b. Subsequent to the implementation of universal immunization against this bacterium, beginning at about 2 mo of age, the incidence of *H. influenzae* type b meningitis dropped precipitously. The median age of bacterial meningitis in the United States increased from age 15 mo in 1986 to 25 yr in 1995. Meningitis now is most commonly caused by *S. pneumoniae* and *N. meningitidis.* However, subsequent to the licensure of conjugated pneumococcal vaccine in 2000 and the recommendation for its universal use beginning at 2 mo of age, the incidence of meningitis caused by this pathogen is decreasing.

Alterations of host defense due to anatomic defects or immune deficits increase the risk of meningitis from less common pathogens such as *Pseudomonas aeruginosa, Staphylococcus aureus,* coagulase-negative staphylococci, *Salmonella* spp, and *L. monocytogenes.*

Epidemiology.

A major risk factor for meningitis is the lack of immunity to specific pathogens associated with young age. Additional risks include recent colonization with pathogenic bacteria, close contact (e.g., household, daycare centers, military

TABLE 594.1-1 -- **Cerebrospinal Fluid Findings in Central Nervous System Disorders**

(Not Available)
PMN = polymorphonuclear neutrophils; CSF = cerebrospinal fluid; EEG = electroencephalogram; HSV = herpes simplex virus; PCR = polymerase chain reaction.

barracks) with individuals having invasive disease caused *by H. influenzae* type b and *N. meningitidis*, crowding, poverty, black race, and male gender. The mode of transmission is probably person to person contact through respiratory tract secretions or droplets. The risk of meningitis is increased among infants and young children with occult bacteremia (see Chapter 162); the odds ratio is greater for meningococcus (85 times) and *H. influenzae* type b (12 times) relative to that for pneumococcus.

Specific host defense defects due to altered immunoglobulin production in response to encapsulated pathogens may be responsible for the increased risk of bacterial meningitis in Native Americans and Eskimos, whereas defects of the complement system (C5-C8) have been associated with recurrent meningococcal infection, and defects of the properdin system have been associated with a significant risk of lethal meningococcal disease. Splenic dysfunction (sickle cell anemia) or asplenia (due to trauma, congenital defect, staging of Hodgkin disease) is associated with an increased risk of pneumococcal, *H. influenzae* type b (to some extent), and, rarely, meningococcal sepsis and meningitis. T-lymphocyte defects (congenital or acquired by chemotherapy, AIDS, or malignancy) are associated with an increased risk of *L. monocytogenes* infections of the CNS.

Congenital or acquired CSF leak across a mucocutaneous barrier, such as cranial or midline facial defects (cribriform plate) and middle ear (stapedial foot plate) or inner ear fistulas (oval window, internal auditory canal, cochlear aqueduct), or CSF leakage through a rupture of the meninges due to a basal skull fracture into the cribriform plate or paranasal sinus, is associated with an increased risk of pneumococcal meningitis. Lumbosacral dermal sinus and meningomyelocele are associated with staphylococcal and gram-negative enteric bacterial meningitis. CSF shunt infections increase the risk of meningitis due to staphylococci (especially coagulase-negative species) and other cutaneous bacteria.

STREPTOCOCCUS PNEUMONIAE.

The epidemiology of infections caused by *S. pneumoniae* is being dramatically altered by the widespread use of conjugated pneumococcal vaccine, licensed in the United States in February 2000. This vaccine is recommended for routine administration to all children 23 mo of age and younger at 2, 4, 6, and 12 to 15 mo of age. Immunization targets this population because the incidence of invasive pneumococcal infections peaks during the first 2 yr of life, reaching rates of 228/100,000 in children 6 to 12 mo of age. Children with anatomic asplenia or functional asplenia secondary to sickle cell disease and those infected with HIV have infection rates that are 20-to 100-fold higher than in those of healthy children during the first 5 years of life. Additional risk factors for contracting pneumococcal meningitis include otitis media, sinusitis, pneumonia, CSF otorrhea or rhinorrhea, and chronic graft versus host disease following bone marrow transplantation.

NEISSERIA MENINGITIDIS.

Meningococcal meningitis may be sporadic or may occur in epidemics. In the United States, serogroups B, C, and Y each account for approximately 30% of cases, although serogroup distribution may vary by location and time. Epidemic disease, especially in developing countries, usually is caused by serogroup A. Cases occur throughout the year but may be more common in the winter and spring. Nasopharyngeal carriage of *N. meningitidis* occurs in 1–15% of adults. Colonization may last weeks to months; recent colonization places nonimmune younger children at greatest risk for meningitis. The incidence of disease occurring in association with an index case in the family is 1%, a rate that is 1,000-fold the risk in the general population. The risk of secondary cases occurring in contacts at daycare centers is about 1/1,000. Most infections of children are acquired from a contact in a daycare facility, a colonized adult family member, or an ill patient with meningococcal disease. College freshmen living in dormitories have an increased incidence of infection compared to noncollege-attending, age-matched controls.

HAEMOPHILUS INFLUENZAE TYPE B.

Before universal *H. influenzae* type b vaccination in the United States, invasive infections occurred primarily in infants 2 mo–2 yr of age; peak incidence was at 6–9 mo of age, and 50% of cases occurred in the 1st yr of life. The risk to children was markedly increased among family or daycare center contacts of patients with *H. influenzae* type b disease. Unvaccinated individuals and those with blunted immunologic responses to vaccine (e.g., children with HIV infection) remain at risk for *H. influenzae* type b meningitis.

Pathology and Pathophysiology.

A meningeal exudate of varying thickness may be distributed around the cerebral veins, venous sinuses, convexity of the brain, and cerebellum and in the sulci, sylvian fissures, basal cisterns, and spinal cord. Ventriculitis with bacteria and inflammatory cells in ventricular fluid may be present, as may subdural effusions and, rarely, empyema. Perivascular inflammatory infiltrates also may be present, and the ependymal membrane may be disrupted. Vascular and parenchymal cerebral changes characterized by polymorphonuclear infiltrates extending to the subintimal region of the small arteries and veins, vasculitis, thrombosis of small cortical veins, occlusion of major venous sinuses, necrotizing arteritis producing subarachnoid hemorrhage, and, rarely, cerebral cortical necrosis in the absence of identifiable thrombosis have been described at autopsy. Cerebral infarction, resulting from vascular occlusion due to inflammation, vasospasm, and thrombosis, is a frequent sequela. Infarct size ranges from microscopic to involvement of an entire hemisphere.

Inflammation of spinal nerves and roots produces meningeal signs, and inflammation of the cranial nerves produces cranial neuropathies of optic, oculomotor, facial, and

auditory nerves. Increased intracranial pressure (ICP) also produces oculomotor nerve palsy due to the presence of temporal lobe compression of the nerve during tentorial herniation. Abducens nerve palsy may be a nonlocalizing sign of elevated ICP.

Increased ICP is due to cell death (cytotoxic cerebral edema), cytokine-induced increased capillary vascular permeability (vasogenic cerebral edema), and, possibly, increased hydrostatic pressure (interstitial cerebral edema) after obstructed reabsorption of CSF in the arachnoid villus or obstruction of the flow of fluid from the ventricles. ICP often exceeds 300?mm H_2O; cerebral perfusion may be further compromised if the cerebral perfusion pressure (mean arterial pressure minus ICP) is less than 50?cm H_2O owing to reduced cerebral blood flow. The syndrome of inappropriate antidiuretic hormone secretion(SIADH) may produce excessive water retention, increasing the risk of elevated ICP. (See Chapter 553.1 .) Hypotonicity of brain extracellular spaces may cause cytotoxic edema after cell swelling and lysis. Tentorial, falx, or cerebellar herniation does not usually occur because the increased ICP is transmitted to the entire subarachnoid space and there is little structural displacement. Furthermore, if the fontanels are still patent, increased ICP is readily dissipated.

Hydrocephalus can occur as an acute complication of bacterial meningitis. It most often takes the form of a communicating hydrocephalus due to adhesive thickening of the arachnoid villi around the cisterns at the base of the brain. Thus, there is interference with the normal resorption of CSF. Less often, obstructive hydrocephalus develops after fibrosis and gliosis of the aqueduct of Sylvius or the foramina of Magendie and Luschka.

Raised CSF protein levels are due in part to increased vascular permeability of the blood-brain barrier and the loss of albumin-rich fluid from the capillaries and veins traversing the subdural space. Continued transudation may result in subdural effusions, usually found in the later phase of acute bacterial meningitis. Hypoglycorrhachia (reduced CSF glucose levels) is due to decreased glucose transport by the cerebral tissue.

Damage to the cerebral cortex may be due to the focal or diffuse effects of vascular occlusion (infarction, necrosis, lactic acidosis),

---

hypoxia, bacterial invasion (cerebritis), toxic encephalopathy (bacterial toxins), elevated ICP, ventriculitis, and transudation (subdural effusions). These pathologic factors result in the clinical manifestations of impaired consciousness, seizures, cranial nerve deficits, motor and sensory deficits, and later psychomotor retardation.

Pathogenesis.

Bacterial meningitis most commonly results from hematogenous dissemination of microorganisms from a distant site of infection; bacteremia usually precedes meningitis or occurs concomitantly. Bacterial colonization of the nasopharynx with a potentially pathogenic microorganism is the usual source of the bacteremia. There may be prolonged carriage of the colonizing organisms without disease or, more likely, rapid invasion after recent colonization. Prior or concurrent viral upper respiratory tract infection may enhance the pathogenicity of bacteria producing meningitis.

N. meningitidis and *H. influenzae* type b attach to mucosal epithelial cell receptors by pili. After attachment to epithelial cells, bacteria breach the mucosa and enter the circulation. *N. meningitidis* may be transported across the mucosal surface within a phagocytic vacuole after ingestion by the epithelial cell. Bacterial survival in the bloodstream is enhanced by large bacterial capsules that interfere with opsonic phagocytosis and are associated with increased virulence. Host-related developmental defects in bacterial opsonic phagocytosis also contribute to the bacteremia. In young, nonimmune hosts, the defect may be due to an absence of preformed IgM or IgG anticapsular antibodies, whereas in immunodeficient patients, various deficiencies of components of the complement or properdin system may interfere with effective opsonic phagocytosis. Splenic dysfunction also may reduce opsonic phagocytosis by the reticuloendothelial system.

Bacteria gain entry to the CSF through the choroid plexus of the lateral ventricles and the meninges and then circulate to the extracerebral CSF and subarachnoid space. Bacteria rapidly multiply because the CSF concentrations of complement and antibody are inadequate to contain bacterial proliferation. Chemotactic factors then incite a local inflammatory response characterized by polymorphonuclear cell infiltration. The presence of bacterial cell wall lipopolysaccharide (endotoxin) of gram-negative bacteria (*H. influenzae* type b, *N. meningitidis*) and of pneumococcal cell wall components (teichoic acid, peptidoglycan) stimulates a marked inflammatory response, with local production of tumor necrosis factor, interleukin-1, prostaglandin E, and other cytokine inflammatory mediators. The subsequent inflammatory response is characterized by neutrophilic infiltration, increased vascular permeability, alterations of the blood-brain barrier, and vascular thrombosis. Excessive cytokine-induced inflammation continues after the CSF has been sterilized and is thought to be partly responsible for the chronic inflammatory sequelae of pyogenic meningitis.

Meningitis rarely may follow bacterial invasion from a contiguous focus of infection such as paranasal sinusitis, otitis media, mastoiditis, orbital cellulitis, or cranial or vertebral osteomyelitis or may occur after introduction of bacteria via penetrating cranial trauma, dermal sinus tracts, or meningomyeloceles. Meningitis may occur during endocarditis, pneumonia, or thrombophlebitis. It also may be associated with severe burns, indwelling catheters, or contaminated infusion equipment.

Clinical Manifestations.

The onset of acute meningitis has two predominant patterns. The more dramatic and, fortunately, less common presentation is sudden onset with rapidly progressive manifestations of shock, purpura, disseminated intravascular coagulation (DIC), and reduced levels of consciousness frequently resulting in death within 24?hr. More often, meningitis is preceded by several days of fever accompanied by upper respiratory tract or gastrointestinal symptoms, followed by nonspecific signs of CNS infection such as increasing lethargy and irritability.

The signs and symptoms of meningitis are related to the nonspecific findings associated with a systemic infection and to manifestations of meningeal irritation. Nonspecific findings include fever, anorexia and poor feeding, symptoms of upper respiratory tract infection, myalgias, arthralgias, tachycardia, hypotension, and various cutaneous signs, such as petechiae, purpura, or an erythematous macular rash. Meningeal irritation is manifested as nuchal rigidity, back pain, Kernig sign (flexion of the hip 90 degrees with subsequent pain with extension of the leg), and Brudzinski sign (involuntary flexion of the knees and hips after passive flexion of the neck while supine). In some children, particularly in those younger than 12–18 mo, Kernig and Brudzinski signs are not consistently present. Increased ICP is suggested by headache, emesis, bulging fontanel or diastasis (widening) of the sutures, oculomotor or abducens nerve paralysis, hypertension with bradycardia, apnea or hyperventilation, decorticate or decerebrate posturing, stupor, coma, or signs of herniation. Papilledema is uncommon in uncomplicated meningitis and should suggest a more chronic process, such as the presence of an intracranial abscess, subdural empyema, or occlusion of a dural venous sinus. Focal neurologic signs usually are due to vascular occlusion. Cranial neuropathies of the ocular, oculomotor, abducens, facial, and auditory nerves also may be due to focal inflammation. Overall, about 10–20% of children with bacterial meningitis have focal neurologic signs.

Seizures (focal or generalized) due to cerebritis, infarction, or electrolyte disturbances occur in 20–30% of patients with meningitis. Seizures that occur on presentation or within the first 4 days of onset are usually of no prognostic significance. Seizures that persist after the 4th day of illness and those that are difficult to treat may be associated with a poor prognosis.

Alterations of mental status are common among patients with meningitis and may be due to increased ICP, cerebritis, or hypotension; manifestations include irritability, lethargy, stupor, obtundation, and coma. Comatose patients have a poor prognosis. Additional manifestations of meningitis include photophobia and tache cérébrale, which is elicited by stroking the skin with a blunt object and observing a raised red streak within 30–60?sec.

Diagnosis.

The diagnosis of acute pyogenic meningitis is confirmed by analysis of the CSF, which typically reveals microorganisms on Gram stain and culture, a neutrophilic pleocytosis, elevated protein, and reduced glucose concentrations (see Table 594–1 (Table Not Available)). LP should be performed when bacterial meningitis is suspected. Contraindications for an immediate LP include (1) evidence of increased ICP (other than a bulging fontanel), such as 3rd or 6th cranial nerve palsy with a depressed level of consciousness, or hypertension and bradycardia with respiratory abnormalities; (2) severe cardiopulmonary compromise requiring prompt resuscitative measures for shock or in patients in whom positioning for the LP would further compromise cardiopulmonary function; and (3) infection of the skin overlying the site of the LP. Thrombocytopenia is a relative contraindication for LP. If an LP is delayed, empirical antibiotic therapy should be initiated. CT scanning for evidence of a brain abscess or increased ICP also should not delay therapy. LP may be performed after increased ICP has been treated or a brain abscess has been excluded.

Blood cultures should be performed in all patients with suspected meningitis. Blood cultures reveal the responsible bacteria in 80–90% of cases of meningitis.

LUMBAR PUNCTURE.

LP usually is performed with a patient in the flexed lateral decubitus position; the styletted needle is passed into the L3-L4 or L4-L5 intervertebral space. After entry into the subarachnoid space, the patient's position is changed to a more extended one to measure the opening CSF pressure, although an accurate reading may not be determined in a crying child. When the pressure is high, only a small volume

---

of CSF should be removed to avoid a precipitous decline in ICP. Also see Chapter 584 .

The CSF leukocyte count in bacterial meningitis is usually elevated to greater than 1,000/mm^3 and typically there is a neutrophilic predominance (75–95%). Turbid CSF is present when the CSF leukocyte count exceeds 200–400/mm^3 . Normal healthy neonates may have as many as 30 leukocytes/mm^3 , but older children without viral or bacterial meningitis have <5 leukocytes/mm^3 in the CSF; in both age groups there is a predominance of lymphocytes or monocytes.

A CSF leukocyte count less than 250/mm^3 may be present in as many as 20% of patients with acute bacterial meningitis; pleocytosis may be absent in patients with severe overwhelming sepsis and meningitis and is a poor prognostic sign. Pleocytosis with a lymphocyte predominance may be present during the early stage of acute bacterial meningitis; conversely, neutrophilic pleocytosis may be present in patients during the early stages of acute viral meningitis. The shift to lymphocytic-monocytic predominance in viral meningitis invariably occurs within 8 to 24?hr of the initial LP. The Gram stain is positive in most (70–90%) patients with bacterial meningitis.

Traumatic LP complicates the diagnosis of meningitis. Repeat LP at a higher interspace may produce less hemorrhagic fluid, but this fluid usually also contains red blood cells. Interpretation of CSF leukocytes and protein concentration are affected by LPs that are traumatic, although the Gram stain, culture, and glucose level may not be influenced. Although methods for correcting for the presence of red blood cells have been proposed, it is prudent to rely on the bacteriologic results rather than to attempt to interpret the CSF leukocyte and protein results of a traumatic LP.

Differential Diagnosis.

In addition to *S. pneumoniae, N. meningitidis,* and *H. influenzae* type b, many other microorganisms can cause generalized infection of the CNS with similar clinical manifestations. These organisms include less typical bacteria, such as

Mycobacterium tuberculosis, Nocardia, Treponema pallidum (syphilis), and *Borrelia burgdorferi* (Lyme disease); fungi, such as those endemic to specific geographic areas (*Coccidioides, Histoplasma,* and *Blastomyces*) and those responsible for infections in compromised hosts (*Candida, Cryptococcus,* and *Aspergillus*); parasites, such as *Toxoplasma gondii* and those that cause cysticercosis and, most frequently, viruses. Focal infections of the CNS including brain abscess and parameningeal abscess (subdural empyema, cranial and spinal epidural abscess) also may be confused with meningitis. Noninfectious illnesses also can cause generalized inflammation of the CNS. Relative to infections, these disorders are uncommon and include malignancy, collagen vascular syndromes, and exposure to toxins.

Determining the specific cause is facilitated by careful examination of the CSF with specific stains (e.g., Kinyoun carbol fuchsin for mycobacteria, India ink for fungi), cytology, antigen detection (bacteria, *Cryptococcus*), serology (syphilis), and viral culture (enterovirus). Other potentially valuable diagnostic tests include CT or MRI of the brain, blood cultures, serologic tests, and possibly brain biopsy. Acute viral meningoencephalitis is the most likely infection to be confused with bacterial meningitis. Although, in general, children with viral meningoencephalitis appear less ill than those with bacterial meningitis, both types of infection have a spectrum of severity. Some children with bacterial meningitis may have relatively mild signs and symptoms, whereas some with viral meningoencephalitis may be critically ill. Although classic CSF profiles associated with bacterial versus viral infection tend to be distinct (see Table 594–1 (Table Not Available)), specific test results may have considerable overlap.

Another diagnostic conundrum in the evaluation of children with suspected bacterial meningitis is the analysis of CSF obtained from children already receiving antibiotic therapy. This is an important issue, because 25–50% of children being evaluated for bacterial meningitis are receiving oral antibiotics when their CSF is obtained. Such partial treatment of a patient with acute bacterial meningitis usually does not substantially alter the typical bacterial CSF profile. Although the frequency of positive CSF Gram stain results and ability to grow the bacteria may be reduced, the concentration of CSF glucose and protein and the neutrophil profile are not substantially altered by pretreatment.

Treatment.

The therapeutic approach to patients with presumed bacterial meningitis depends on the nature of the initial manifestations of the illness. A child with rapidly progressing disease of less than 24-hr duration, in the absence of increased ICP, should receive antibiotics immediately after an LP is performed. If there are signs of increased ICP or focal neurologic findings, antibiotics should be given without performing an LP and before obtaining a CT scan. Increased ICP should be treated simultaneously. Immediate treatment of associated multiple organ system failure, such as shock and adult respiratory distress syndrome, also is indicated.

Patients who have a more protracted subacute course and become ill over a 1–7 day period should also be evaluated for signs of increased ICP and focal neurologic deficits. Unilateral headache, papilledema, and other signs of increased ICP suggest a focal lesion such as a brain or epidural abscess, or subdural empyema. Under these circumstances, antibiotic therapy should be initiated before LP and CT scanning. If no signs of increased ICP are evident, an LP should be performed.

INITIAL ANTIBIOTIC THERAPY.

The initial (empirical) choice of therapy for meningitis in immunocompetent infants and children is primarily determined by the antibiotic susceptibilities of *S. pneumoniae*. Selected antibiotics should achieve bactericidal levels in the CSF. Although there are substantial geographic differences in the frequency of resistance of *S. pneumoniae* to antibiotics, rates are increasing throughout the world. In the United States, 25–50% of strains of *S. pneumoniae* are currently resistant to penicillin; relative resistance (MIC, 0.1–1.0?ug/mL) is more common than high-level resistance (MIC = 2.0?ug/mL). Resistance to cefotaxime and ceftriaxone also is evident in up to 25% of isolates. In contrast, most strains of *N. meningitidis* are sensitive to penicillin and cephalosporins, although rare resistant isolates have been reported. Approximately 30–40% of isolates of *H. influenzae* type b produce ß-lactamases and therefore are resistant to ampicillin. These ß-lactamase-producing strains remain sensitive to the extended-spectrum cephalosporins.

Based on the substantial rate of resistance of *S. pneumoniae* to ß-lactam drugs recommended empirical therapy is vancomycin (60?mg/kg/24?hr, given every 6?hr) in combination with either of the third-generation cephalosporins, cefotaxime (200?mg/kg/24?hr, given every 6?hr) or ceftriaxone (100?mg/kg/24?hr administered once per day or 50?mg/kg/dose, given every 12?hr). Patients allergic to ß-lactam antibiotics can be treated with chloramphenicol, 100?mg/kg/24?hr, given every 6?hr.

If *L. monocytogenes* infection is suspected, as in infants 1–2 mo old or patients with a T-lymphocyte deficiency, ampicillin (200?mg/kg/24?hr, given every 6?hr) should be given with ceftriaxone or cefotaxime because cephalosporins are inactive against *L. monocytogenes.* Intravenous trimethoprim-sulfamethoxazole is an alternative treatment for *L. monocytogenes.*

If a patient is immunocompromised and gram-negative bacterial meningitis is suspected, initial therapy might include ceftazidime and an aminoglycoside.

DURATION OF ANTIBIOTIC THERAPY.

Therapy for uncomplicated penicillin-sensitive *S. pneumoniae* meningitis should be completed with a third-generation cephalosporin or intravenous penicillin (400,000?U/kg/24?hr, given every 4–6?hr) for 10–14 days. If the isolate is resistant to penicillin and the third-generation cephalosporin, therapy should be completed with vancomycin. Intravenous penicillin (400,000?U/kg/24?hr) for

5–7 days is the treatment of choice for uncomplicated *N. meningitidis* meningitis. Uncomplicated *H. influenzae* type b meningitis should be treated for a total of 7–10 days. Ampicillin should be used to complete the course of therapy if the isolate is found to be sensitive.

Patients who receive intravenous or oral antibiotics before LP and who do not have an identifiable pathogen but do have evidence of an acute bacterial infection on the basis of their CSF profile should continue to receive therapy with ceftriaxone or cefotaxime for 7–10 days. If focal signs are present or the child does not respond to treatment, a parameningeal focus may be present and a CT or MRI scan should be performed.

A routine repeat LP is not indicated in patients with uncomplicated meningitis due to antibiotic-sensitive *S. pneumoniae, N. meningitidis,* or *H. influenzae* type b. Repeat examination of CSF is indicated in some neonates, in patients with gram-negative bacillary meningitis, or in infection caused by a ß-lactam-resistant *S. pneumoniae.* The CSF should be sterile within 24–48?hr of initiation of appropriate antibiotic therapy.

Meningitis due to *Escherichia coli* or *P. aeruginosa* requires therapy with a third-generation cephalosporin active against the isolate in vitro. Most isolates of *E. coli* are sensitive to cefotaxime or ceftriaxone, and most isolates of *P. aeruginosa* are sensitive to ceftazidime. Gram-negative bacillary meningitis should be treated for 3 wk or for at least 2 wk after CSF sterilization, which may occur after 2–10 days of treatment.

Side effects of antibiotic therapy of meningitis include phlebitis, drug fever, rash, emesis, oral candidiasis, and diarrhea. Ceftriaxone may cause reversible gallbladder pseudolithiasis, detectable by abdominal ultrasonography. This is usually asymptomatic but may be associated with emesis and right upper quadrant pain.

CORTICOSTEROIDS.

Rapid killing of bacteria in the CSF effectively sterilizes the meningeal infection but releases toxic cell products after cell lysis (cell wall endotoxin) that precipitates the cytokine-mediated inflammatory response. The resultant edema formation and neutrophilic infiltration may produce additional neurologic injury with worsening of CNS signs and symptoms. Therefore, agents that limit production of inflammatory mediators may be of benefit to patients with bacterial meningitis.

Data support the use of intravenous dexamethasone, 0.15?mg/kg/dose given every 6?hr for 2 days, in the treatment of children older than 6 wk with acute bacterial meningitis caused by *H. influenzae* type b. However, data are inconclusive regarding the benefit, if any, of corticosteroids in the treatment of meningitis caused by other bacteria. Therefore, their use is controversial. Among children with meningitis due *H. influenzae* type b, corticosteroid recipients had less fever, lower CSF protein and lactate levels, and a reduction in permanent auditory nerve damage, as manifested by sensorineural hearing loss, than did placebo recipients, enrolled in randomized, controlled trials. Corticosteroids appear to have maximum benefit if given 1–2?hr before antibiotics were initiated. Corticosteroids are not harmless; complications of their use may include gastrointestinal bleeding, hypertension, hyperglycemia, leukocytosis, and rebound fever, after the last dose.

SUPPORTIVE CARE.

Repeated medical and neurologic assessments of patients with bacterial meningitis are essential to identify early signs of cardiovascular, CNS, and metabolic complications. Pulse rate, blood pressure, and respiratory rate should be monitored frequently. Neurologic assessment, including pupillary reflexes, level of consciousness, motor strength, cranial nerve signs, and evaluation for seizures, should be made frequently during the first 72?hr, when the risk of neurologic complications is greatest. Important laboratory studies include an assessment of blood urea nitrogen; serum sodium, chloride, potassium, and bicarbonate levels; urine output and specific gravity; complete blood and platelet counts; and, in the presence of petechiae, purpura, or abnormal bleeding, measure of coagulation function (fibrinogen, prothrombin, and partial thromboplastin times).

Patients should initially receive nothing by mouth. If a patient is judged to be normovolemic, with normal blood pressure, intravenous fluid administration should be restricted to one half to two thirds of maintenance, or 800–1,000?mL/m^2 /24?hr, until it can be established that increased ICP or SIADH is not present. Fluid administration may be returned to normal (1,500–1,700?mL/m^2 /24?hr) when serum sodium levels are normal. Fluid restriction is not appropriate in the presence of systemic hypotension because reduced blood pressure may result in reduced cerebral perfusion pressure and CNS ischemia. Therefore, shock must be treated aggressively to prevent brain and other organ dysfunction (acute tubular necrosis, adult respiratory distress syndrome). Patients with shock, a markedly elevated ICP, coma, and refractory seizures require intensive monitoring with central arterial and venous access and frequent vital signs, necessitating admission to a pediatric intensive care unit. Patients with septic shock require fluid resuscitation and therapy with vasoactive agents such as dopamine, epinephrine, and sodium nitroprusside (Chapter 163). The goal of such therapy in patients with meningitis is to avoid excessive increases in ICP without compromising blood flow and oxygen delivery to vital organs.

Neurologic complications include increased ICP with subsequent herniation, seizures, and an enlarging head circumference due to a subdural effusion or hydrocephalus. Signs of increased ICP should be treated emergently with endotracheal intubation and hyperventilation (to maintain the PCO_2 at approximately 25?mm?Hg). In addition, intravenous furosemide (Lasix, 1?mg/kg) and mannitol (0.5–1?g/kg) osmotherapy may reduce ICP (Chapter 57.7). Furosemide may reduce brain swelling by venodilation and diuresis without increasing intracranial blood volume, whereas mannitol produces an osmolar gradient between the brain and plasma, thus shifting fluid from the CNS to the plasma, with subsequent excretion during an osmotic diuresis.

Seizures are common during the course of bacterial meningitis. Immediate therapy for seizures includes intravenous diazepam (0.1–0.2?mg/kg/dose) or lorazepam (0.05?mg/kg/dose), paying careful attention to the risk of respiratory suppression. Serum glucose, calcium, and sodium levels should be monitored to rule out a metabolic etiology. After immediate management of seizures, patients should receive phenytoin (15–20?mg/kg loading dose, 5?mg/kg/24?hr maintenance) to reduce the likelihood of recurrence. Phenytoin is preferred to phenobarbital because it produces less CNS depression and permits assessment of a patient's level of consciousness. Serum phenytoin levels should be monitored to maintain them in the therapeutic

range (10–20?µg/mL).

Complications.

During the treatment of meningitis, acute CNS complications can include seizures, increased ICP, cranial nerve palsies, stroke, cerebral or cerebellar herniation, and thrombosis of the dural venous sinuses.

Collections of fluid in the subdural space develop in 10–30% of patients with meningitis and are asymptomatic in 85–90% of patients. Subdural effusions are especially common in infants. Symptomatic subdural effusions may result in a bulging fontanel, diastasis of sutures, enlarging head circumference, emesis, seizures, fever, and abnormal results of cranial transillumination. CT or MRI scanning confirms the presence of a subdural effusion. In the presence of increased ICP or a depressed level of consciousness, symptomatic subdural effusion should be treated by aspiration through the open fontanel. Fever alone is not an indication for aspiration.

SIADH occurs in the majority of patients with meningitis, resulting in hyponatremia and reduced serum osmolality in

30–50% of infected children. This may exacerbate cerebral edema or independently produce hyponatremic seizures.

Fever associated with bacterial meningitis usually resolves within 5–7 days of the onset of therapy. Prolonged fever (>10 days) is noted in about 10% of patients. Prolonged fever usually is due to intercurrent viral infection, nosocomial or secondary bacterial infection, thrombophlebitis, or drug reaction. Secondary fever refers to the recrudescence of elevated temperature after an afebrile interval. Nosocomial infections are especially important to consider in the evaluation of these patients. Pericarditis or arthritis may occur in patients being treated for meningitis. Involvement of these sites may result either from bacterial dissemination or from immune complex deposition. In general, infectious pericarditis or arthritis occurs earlier in the course of treatment than does immune-mediated disease.

Thrombocytosis, eosinophilia, and anemia may develop during therapy for meningitis. Anemia may be due to hemolysis or bone marrow suppression. DIC is most often associated with the rapidly progressive pattern of presentation and is noted most commonly in patients with shock and purpura. The combination of endotoxemia and severe hypotension initiates the coagulation cascade; the coexistence of ongoing thrombosis may produce symmetric peripheral gangrene.

Prognosis.

Appropriate recognition, prompt antibiotic therapy, and supportive care have reduced the mortality of bacterial meningitis after the neonatal period to less than 10%. The highest mortality rates are observed with pneumococcal meningitis. Severe neurodevelopmental sequelae may occur in 10–20% of patients recovering from bacterial meningitis, and as many as 50% have some, albeit subtle, neurobehavioral morbidity. The prognosis is poorest among infants younger than 6 mo and in those with more than 10^6 colony-forming units of bacteria/mL in their CSF. Those with seizures occurring more than 4 days into therapy or with coma or focal neurologic signs on presentation have an increased risk of long-term sequelae. There does not appear to be a correlation between duration of symptoms before diagnosis of meningitis and outcome.

The most common neurologic sequelae include hearing loss, mental retardation, seizures, delay in acquisition of language, visual impairment, and behavioral problems. Sensorineural hearing loss is the most common sequela of bacterial meningitis. It is due to labyrinthitis following cochlear infection and occurs in as many as 30% of patients with pneumococcal meningitis, 10% with meningococcal, and 5–20% of those with *H. influenzae* type b meningitis. Hearing loss also may be due to direct inflammation of the auditory nerve. All patients with bacterial meningitis should undergo careful audiologic assessment before or soon after discharge from the hospital. Frequent reassessment on an outpatient basis is indicated for patients who have a hearing deficit.

Prevention.

Vaccination and antibiotic prophylaxis of susceptible at-risk contacts represent the two available means of reducing the likelihood of bacterial meningitis. The availability and application of each of these approaches depend upon the specific infecting bacteria.

NEISSERIA MENINGITIDIS.

Chemoprophylaxis is recommended for all close contacts of patients with meningococcal meningitis regardless of age or immunization status. Close contacts should be treated with rifampin 10?mg/kg/dose every 12?hr (maximum dose of 600?mg) for 2 days as soon as possible after identification of a case of suspected meningococcal meningitis or sepsis. Close contacts include household, daycare center, and nursery school contacts and health care workers who have direct exposure to oral secretions (e.g., mouth-to-mouth resuscitation, suctioning, intubation). Exposed contacts should be treated immediately on suspicion of infection in the index patient; bacteriologic confirmation of infection should not be awaited. In addition, all contacts should be educated about the early signs of meningococcal disease and the need to seek prompt medical attention if these signs develop.

Meningococcal quadrivalent vaccine against serogroups A, C, Y, and W135 is recommended for high-risk children older than 2 yr. High-risk patients include those with anatomic or functional asplenia or deficiencies of terminal complement proteins. Use of meningococcal vaccine should be considered for college freshmen, especially those who live in dormitories, because of an observed increased risk of invasive meningococcal infections compared to the risk in noncollege-attending, age-matched controls. The vaccine also may be used as an adjunct with chemoprophylaxis for exposed contacts and during epidemics of meningococcal disease.

HAEMOPHILUS INFLUENZAE TYPE B.

Rifampin prophylaxis should be given to all household contacts, including adults, if any close family member younger than 48 mo has not been fully immunized or if an immunocompromised child resides in the household. A household contact is one who lives in the residence of the index case or who has spent a minimum of 4?hr with the index case for at least 5 of 7 days preceding the patient's hospitalization. Family members should receive rifampin prophylaxis immediately after the diagnosis is suspected in the index case because more than 50% of secondary family cases occur in the 1st wk after the index patient has been hospitalized.

The dose of rifampin is 20?mg/kg/24?hr (maximum dose of 600?mg) given once each day for 4 days. Rifampin discolors the urine and sweat red-orange, stains contact lenses, and reduces the serum concentrations of some drugs, including oral contraceptives. Rifampin is contraindicated during pregnancy.

The most striking advance in the prevention of childhood bacterial meningitis followed the development and licensure of vaccines against *H. influenzae* type b. Four conjugate vaccines are licensed in the United States. Although each vaccine elicits different profiles of antibody response in infants immunized at 2–6 mo of age, all result in protective levels of antibody with efficacy rates, against invasive infections, that range from 70–100%. Efficacy is not as consistent in Native American populations, a group recognized as having an extremely high incidence of disease. All children should be immunized with *H. influenzae* type b conjugate vaccine beginning at 2 mo of age. See Chapter 282 .

STREPTOCOCCUS PNEUMONIAE.

A heptavalent conjugate vaccine against *S. pneumoniae* was licensed for use in the United States in 2000. Routine administration of this vaccine is recommended for all children younger than 2 yr of age. The initial dose is given at approximately 2 mo of age. Children who are at high risk of invasive pneumococcal infections should also receive the vaccine, including those with functional or anatomic asplenia and those with underlying immunodeficiency, such as infection with HIV, primary immunodeficiency, and those receiving immunosuppressive therapy.

594.2 Viral Meningoencephalitis

Viral meningoencephalitis is an acute inflammatory process involving the meninges and, to a variable degree, brain tissue. These infections are relatively common and may be caused by a number of different agents. The CSF is characterized by pleocytosis and the absence of microorganisms on Gram stain and routine bacterial culture. In most instances, the infections are self-limited. However, in some cases, substantial morbidity and mortality occur.

Etiology.

Enteroviruses cause more than 80% of all cases of meningoencephalitis. Enteroviruses are small RNA-containing viruses; more than 80 serotypes have been identified. The severity of disease ranges from mild, self-limited illness with primarily meningeal involvement to severe encephalitis with death or significant sequelae.

Arboviruses are arthropod-borne agents, responsible for some cases of meningoencephalitis during summer months. Mosquitoes and ticks are the most common vectors, spreading disease to humans and other vertebrates, such as horses, after biting infected birds or small animals. Encephalitis in horses (“blind staggers”) may be the first indication of an incipient epidemic. Although rural exposure is most common, urban and suburban outbreaks are also frequent. The most common arboviruses responsible for CNS infection in the United States are St. Louis and California encephalitis viruses (Chapter 244). West Nile virus recently made its appearance in the Western hemisphere, causing two successive outbreaks of encephalitis in 1999 and 2000 in the northeastern United States. Although most of the 78 cases during these two epidemics were in adults, two children were hospitalized. The incidence of West Nile virus infections continues to increase across the United States.

Several members of the herpes family of viruses can cause meningoencephalitis. Herpes simplex virus type 1 (HSV-1) is an important cause of severe, sporadic encephalitis in children and adults. Brain involvement usually is focal; progression to coma and death occurs in 70% of cases without antiviral therapy. Severe encephalitis with diffuse brain involvement is caused by herpes simplex virus type 2 (HSV-2) in neonates who usually contract the virus from their mothers at delivery. A mild transient form of meningoencephalitis may accompany genital herpes infection in sexually active adolescents; most of these infections are caused by HSV-2. Varicella-zoster virus (VZV) may cause CNS infection in close temporal relationship

with chickenpox. The most common manifestation of CNS involvement is cerebellar ataxia, and the most severe is an acute encephalitis. After primary infection, VZV becomes latent in spinal and cranial nerve roots and ganglia, expressing itself later as herpes zoster, often with accompanying mild meningoencephalitis. Cytomegalovirus (CMV) infection of the CNS may be part of congenital infection or disseminated disease in immunocompromised hosts, but it does not cause meningoencephalitis in normal infants and children. Epstein-Barr virus (EBV) has been associated with myriad CNS syndromes (Chapter 233).

Mumps is a common pathogen in regions where mumps vaccine is not widely used. Mumps meningoencephalitis is mild, but deafness due to damage of the 8th cranial nerve may be a sequela. Meningoencephalitis is caused occasionally by respiratory viruses, rubeola, rubella, or rabies.

Epidemiology.

The epidemiologic pattern of viral meningoencephalitis is primarily determined by the prevalence of enteroviruses, the most common etiology. Infection with enteroviruses is spread directly from person to person, with a usual incubation period of 4–6 days. Most cases in temperate climates occur in the summer and fall. Epidemiologic considerations in aseptic meningitis due to agents other than enteroviruses also include season, geography, climatic conditions, animal exposures, and factors related to the specific pathogen.

Pathogenesis.

Neurologic damage is caused by direct invasion and destruction of neural tissues by actively multiplying viruses or by a host reaction to viral antigens. Most neuronal destruction is probably due directly to viral invasion, whereas the host's vigorous tissue response induces demyelination and vascular and perivascular destruction.

Tissue sections of the brain generally are characterized by meningeal congestion and mononuclear infiltration, perivascular cuffs of lymphocytes and plasma cells, some perivascular tissue necrosis with myelin breakdown, and neuronal disruption in various stages, including ultimately neuronophagia and endothelial proliferation or necrosis. A marked degree of demyelination with preservation of neurons and their axons is considered predominantly to represent “postinfectious” or “allergic” encephalitis. The cerebral cortex, especially the temporal lobe, is often severely affected by HSV; the arboviruses tend to affect the entire brain; rabies has a predilection for the basal structures. Involvement of the spinal cord, nerve roots, and peripheral nerves is variable.

Clinical Manifestations.

The progression and severity of disease are determined by the relative degree of meningeal and parenchymal involvement, which in part is determined by the specific etiology. However, the clinical course resulting from infection with the same pathogen varies widely. Some children may appear to be mildly affected initially, only to lapse into coma and die suddenly. In others, the illness may be ushered in by high fever, violent convulsions interspersed with bizarre movements, and hallucinations alternating with brief periods of clarity, followed by complete recovery.

The onset of illness is generally acute, although CNS signs and symptoms often are preceded by a nonspecific febrile illness of a few days' duration. The presenting manifestations in older children are headache and hyperesthesia, and in infants, irritability and lethargy. Headache is most often frontal or generalized; adolescents frequently complain of retrobulbar pain. Fever, nausea and vomiting, photophobia, and pain in the neck, back, and legs are common. As body temperature increases, there may be mental dullness, progressing to stupor in combination with bizarre movements and convulsions. Focal neurologic signs may be stationary, progressive, or fluctuating. Loss of bowel and bladder control and unprovoked emotional bursts may occur.

Exanthems often precede or accompany the CNS signs, especially with echoviruses, coxsackieviruses, VZV, measles, and rubella. Examination often reveals nuchal rigidity without significant localizing neurologic changes, at least at the onset.

Specific forms or complicating manifestations of CNS viral infection include Guillain-Barré syndrome, transverse myelitis, hemiplegia, and cerebellar ataxia.

Diagnosis.

The diagnosis of viral encephalitis is usually made on the basis of the clinical presentation of nonspecific prodrome followed by progressive CNS symptoms. The diagnosis is supported by examination of the CSF, which usually shows a mild mononuclear predominance (see Table 594–1 (Table Not Available)). Other tests of potential value in the evaluation of patients with suspected viral meningoencephalitis include an electroencephalogram (EEG) and neuroimaging studies. The EEG typically shows diffuse slow-wave activity, usually without focal changes. Neuroimaging studies (CT or MRI) may show swelling of the brain parenchyma. Focal seizures or focal findings on EEG or CT or MRI, especially involving the temporal lobes, suggest HSV encephalitis.

Differential Diagnosis.

A number of clinical conditions that cause CNS inflammation mimic viral meningoencephalitis. The most important group of alternative infectious agents to consider is bacteria. Most children with acute bacterial meningitis appear more critically ill than those with CNS viral infection. Parameningeal bacterial infections, such as brain abscess or subdural or epidural empyema, may have features similar to viral CNS infections. Infections caused by *M. tuberculosis*, *T. pallidum* (syphilis), *Borrelia burgdorferi* (Lyme disease), and *Bartonella henselae,* the bacillus associated with cat-scratch disease, tend to result in indolent courses. Analysis of CSF and appropriate serologic tests are necessary to differentiate these various pathogens.

Infections due to fungi, rickettsiae, *Mycoplasma,* protozoa, and other parasites also need to be included in the differential diagnosis. Consideration of these agents usually arises as a result of accompanying symptoms, geographic locality of infection, or host immune factors.

Various noninfectious disorders may be associated with CNS inflammation and have

manifestations overlapping with those associated with viral meningoencephalitis. Some of these

disorders include malignancy, collagen vascular diseases, intracranial hemorrhage, and exposure to certain drugs or toxins. Attention to history and other organ involvement usually allows elimination of these diagnostic possibilities.

Laboratory Findings.

The CSF contains from a few to several thousand cells per cubic millimeter. Early in the disease, the cells are often polymorphonuclear; later, mononuclear cells predominate. This change in cellular type is often demonstrated in CSF samples obtained as little as 8–12?hr apart. The protein concentration in CSF tends to be normal or slightly elevated, but concentrations may be very high if brain destruction is extensive, such as that caused by HSV encephalitis. The glucose level is usually normal, although with certain viruses, for example, mumps, a substantial depression of CSF glucose concentrations may be observed.

The CSF should be cultured for viruses, bacteria, fungi, and mycobacteria; in some instances, special examinations are indicated for protozoa, *Mycoplasma,* and other pathogens. The success of isolating viruses from the CSF of children with viral meningoencephalitis is determined by the time in the clinical course that the specimen is obtained, the specific etiologic agent, whether the infection is a meningitic as opposed to a localized encephalitic process, and the skill of the diagnostic laboratory. Isolating a virus is most likely early in the illness, and the enteroviruses tend to be the easiest to isolate, although recovery of these agents from the CSF rarely exceeds 70%. To increase the likelihood of identifying the putative viral pathogen, specimens for culture also should be obtained from nasopharyngeal swabs, feces, and urine. Although isolating a virus from one or more of these sites does not prove causality, it is highly suggestive.

A serum specimen should be obtained early in the course of illness and, if viral cultures are not diagnostic, again 2–3 wk later for serologic studies. Serologic methods are not practical for diagnosing CNS infections caused by the enteroviruses because there are too many serotypes. However, this approach may be useful to confirm that a case is caused by a known circulating viral type. Serologic tests also may be of value in determining the etiology of nonenteroviral CNS infection. Detection of viral DNA or RNA by polymerase chain reaction may be useful in the diagnosis of CNS infection caused by HSV and enteroviruses, respectively.

Treatment.

With the exception of the use of acyclovir for HSV encephalitis, treatment of viral meningoencephalitis is supportive. Treatment of mild disease may require only symptomatic relief. Headache and hyperesthesia are treated with rest, non-aspirin–containing analgesics, and a reduction in room light, noise, and visitors. Acetaminophen is recommended for fever. Codeine, morphine, and the phenothiazine derivatives may be necessary for pain and vomiting, but if possible, their use in children should be minimized because they may induce misleading signs and symptoms. Intravenous fluids are occasionally necessary because of poor oral intake. More severe disease may require hospitalization and intensive care.

It is important to anticipate and be prepared to manage convulsions, cerebral edema, hyperpyrexia, inadequate respiratory exchange, disturbed fluid and electrolyte balance, aspiration and asphyxia, and cardiac or respiratory arrest of central origin. Therefore, all patients with severe encephalitis should be monitored closely. In patients with evidence of increased ICP, placement of a pressure transducer in the epidural space may be indicated. The risks of cardiac and respiratory failure or arrest are high with severe disease. All fluids, electrolytes, and medications are initially given parenterally. In prolonged states of coma, parenteral alimentation is indicated. SIADH is common in acute CNS disorders; frequent monitoring of serum sodium concentrations is required for early detection (see Chapter 553.1). Normal blood levels of glucose, magnesium, and calcium must be maintained to minimize the likelihood of convulsions. If cerebral edema or seizures become evident, vigorous treatment should be instituted.

Prognosis.

Supportive and rehabilitative efforts are very important after patients recover. Motor incoordination, convulsive disorders, total or partial deafness, and behavioral disturbances may follow viral CNS infections. Visual disturbances due to chorioretinopathy and perceptual amblyopia also may occur. Special facilities and, at times, institutional placement may become necessary. Some sequelae of infection may be very subtle. Therefore, neurodevelopmental and audiologic evaluations should be part of the routine follow-up of children who have recovered from viral meningoencephalitis.

Most children completely recover from viral infections of the CNS, although the prognosis depends on the severity of the clinical illness, the specific cause, and the age of the child. If the clinical illness is severe and substantial parenchymal involvement is evident, the prognosis is poor, with potential deficits being intellectual, motor, psychiatric, epileptic, visual, or auditory in nature. Severe sequelae also should be anticipated in those with infection caused by HSV. Although some literature suggests that infants who contract viral meningoencephalitis have a poorer long-term outcome than older children, other data refute this observation. Approximately 10% of children younger than 2 yr with enteroviral CNS infections suffer an acute complication such as seizures, increased ICP, or coma. However, almost all have favorable long-term neurologic outcomes.

Prevention.

Widespread use of effective viral vaccines for polio, measles, mumps, rubella, and varicella has almost eliminated CNS complications from these diseases in the United States. The availability of domestic animal vaccine programs against rabies has reduced the frequency of rabies encephalitis. Control of encephalitis due to arboviruses has been less successful because specific vaccines for the arboviral diseases that occur in North America are not available. However, control of insect vectors by suitable spraying methods and eradication of insect breeding sites

reduces the incidence of these infections.

594.3 Eosinophilic Meningitis

Eosinophilic meningitis is defined as 10 or more eosinophils/mm^3 of CSF. The most common cause worldwide of eosinophilic pleocytosis is CNS infection with helminthic parasites. However, in countries such as the United States, where helminthic infestation is uncommon, the differential diagnosis of CSF eosinophilic pleocytosis is broad.

Etiology.

Although any tissue-migrating helminth may cause eosinophilic meningitis, the most common cause is human infection with the rat lungworm *Angiostrongylus cantonensis* (Chapter 274). Other parasites that can cause eosinophilic meningitis include *Gnathostoma spinigerum* (dog and cat roundworm) (Chapter 274), *Baylisascaris procyonis* (raccoon roundworm), *Ascaris lumbricoides* (human roundworm), *Trichinella spiralis, Toxocara canis, Toxoplasma gondii, Paragonimus westermani, Echinococcus granulosus, Schistosoma japonicum, Onchocerca volvulus,* and *T. solium.* Eosinophilic meningitis also may occur as an unusual manifestation of more common viral, bacterial, or fungal infections of the CNS. Noninfectious causes of eosinophilic meningitis include multiple sclerosis, malignancy, hypereosinophilic syndrome, or a reaction to medications or a ventriculoperitoneal shunt.

Epidemiology.

A. cantonensis is found in Southeast Asia, the South Pacific, Japan, Taiwan, Egypt, Ivory Coast, and Cuba. Infection is acquired by eating raw or undercooked freshwater snails, slugs, prawns, or crabs containing infectious third-stage larvae. *Gnathostoma* infections are found in Japan, China, India,

---

Bangladesh, and Southeast Asia. Gnathostomiasis is acquired by eating undercooked or raw fish, frog, bird, or snake meat.

Clinical Manifestations.

When eosinophilic meningitis results from helminthic infestation, patients become ill 1–3 wk after exposure, because the parasites migrate from the gastrointestinal tract to the CNS. Common concomitant findings include fever, peripheral eosinophilia,

vomiting, abdominal pain, creeping skin eruptions, or pleurisy. Neurologic symptoms may include headache, meningismus, ataxia, cranial nerve palsies, and paresthesias. Paraparesis or incontinence can result from radiculitis or myelitis.

Diagnosis.

The presumptive diagnosis of helminth-induced eosinophilic meningitis is made by travel and exposure history in the presence of typical clinical and laboratory findings.

Treatment.

Treatment is supportive, because infection is self-limited and anthelmintic drugs do not appear to influence the outcome of infection. Analgesics should be given for headache and radiculitis, and CSF removal or shunting should be performed to relieve hydrocephalus, if present. Steroids may decrease the duration of headaches in adults with eosinophilic meningitis.

Prognosis.

The prognosis is good; 70% of patients improve sufficiently to leave the hospital in 1–2 wk. Mortality associated with eosinophilic meningitis is less than 1%.

Chapter 595 - Brain Abscess

Robert H. A. Haslam

Brain abscesses can occur in children of any age but are most common in children between 4 and 8 yr. The causes of brain abscess include embolization due to congenital heart disease with right-to-left shunts (especially tetralogy of Fallot), meningitis, chronic otitis media and mastoiditis, sinusitis, soft tissue infection of the face or scalp, orbital cellulitis, dental infections, penetrating head injuries, immunodeficiency states, and infection of ventriculoperitoneal shunts. The pathogenesis is undetermined in 10–15% of cases. Cerebral abscesses are evenly distributed between the two hemispheres, and approximately 80% of cases are divided equally between the frontal, parietal, and temporal lobes. Brain abscesses in the occipital lobe, cerebellum, and brainstem account for about 20% of the cases. Most brain abscesses are single, but 30% are multiple and may involve more than one lobe. An abscess in the frontal lobe is often caused by extension from sinusitis or orbital cellulitis, whereas abscesses located in the temporal lobe or cerebellum are frequently associated with chronic otitis media and mastoiditis. Abscesses resulting from penetrating injuries tend to be singular and caused by *Staphylococcus aureus*, whereas those resulting from septic emboli, congenital heart disease, or meningitis often have several causal organisms.

Etiology.

The responsible bacteria include *S. aureus*, streptococci (*viridans*, pneumococci, microaerophilic), anaerobic organisms (gram-positive cocci, *Bacteroides* spp, *Fusobacterium* spp, *Prevotella* spp, *Actinomyces* spp, and *Clostridium* spp), and gram-negative aerobic bacilli (enteric rods, *Proteus* spp, *Pseudomonas aeruginosa*, *Citrobacter diversus*, and *Haemophilus* spp). One organism is cultured in the majority of abscesses (70%), two in 20%, and three or more in 10% of cases. Abscesses associated with mucosal infections (sinusitis) frequently have anaerobic bacteria.

Clinical Manifestations.

The early stages of cerebritis and abscess formation are associated with nonspecific symptoms, including low-grade fever, headache, and lethargy. The significance of these symptoms is generally not recognized, and an oral antibiotic is often prescribed with resultant transient relief. As the inflammatory process proceeds,

vomiting, severe headache, seizures, papilledema, focal neurologic signs (hemiparesis), and coma may develop. A cerebellar abscess is characterized by nystagmus, ipsilateral ataxia and dysmetria, vomiting, and headache. If the abscess ruptures into the ventricular cavity, overwhelming shock and death usually ensue.

Diagnosis.

The peripheral white blood cell count can be normal or elevated, and the blood culture is positive in approximately 10% of cases. Examination of the cerebrospinal fluid (CSF) shows variable results; the white blood cells and protein may be minimally elevated or normal. The glucose level may be slightly low, and CSF cultures are rarely positive. Aspiration of the abscess is much more likely to establish a bacteriologic diagnosis. Because examination of the CSF is seldom useful and a

lumbar puncture may cause herniation of the cerebellar tonsils, the procedure should not be undertaken in a child suspected of having a brain abscess. The electroencephalogram (EEG) shows corresponding focal slowing, and the radionuclide brain scan indicates an area of enhancement due to disruption of the blood-brain barrier in greater than 80% of cases. CT and MRI are the most reliable methods of demonstrating cerebritis and abscess formation (Fig. 595–1). The CT findings of cerebritis are characterized by a parenchymal low-density lesion, and MRI T2 weighted images indicate increased signal intensity. An abscess cavity shows a ring-enhancing lesion by contrast CT, and the MRI also demonstrates an abscess capsule with gadolinium administration.

Treatment.

The initial management of a brain abscess includes prompt diagnosis and institution of an antibiotic regimen that is based on the probable pathogenesis and most likely organism. When the cause is unknown, the dual combination of a third-generation cephalosporin and metronidazole is commonly used. If there is a history of head trauma or neurosurgery, a combination of nafcillin or vancomycin with a third-generation cephalosporin and metronidazole is given. The choice of antibiotics should be altered when the culture and sensitivity results become available. An abscess resulting from a penetrating injury, head trauma, or sinusitis should be treated with a combination of nafcillin or vancomycin, cefotaxime or ceftriaxone, and metronidazole. Monotherapy with meropenem, which has good activity against gram-negative bacilli, anaerobes, staphylococci, and streptococci, including virtually all antibiotic-resistant pneumococci, is a reasonable alternative. In contrast, the initial treatment of a lesion resulting from cyanotic heart disease is penicillin and metronidazole. Abscesses secondary to an infected ventriculoperitoneal shunt may be initially treated with vancomycin and ceftazidime. When otitis media, sinusitis, or mastoiditis is the likely cause, vancomycin, because of the increasing incidence of penicillin resistance among *S. pneumoniae*, in combination with a third-generation cephalosporin and metronidazole is initially

Figure 595-1 CT with contrast. Note the large wall-enhancing abscess in the left frontal lobe. The lesion is causing a shift of the brain to the right. The patient had no neurologic signs until just before the CT scan because the abscess is located in the frontal lobe, a “silent” area of the brain.

indicated until the culture results become available. When *Citrobacter* meningitis (often in neonates) leads to abscess formation, a third-generation cephalosporin is used, typically in combination with an aminoglycoside. In immunocompromised patients, broad-spectrum antibiotic coverage is used, and amphotericin B therapy should be considered.

Surgical management of brain abscesses has changed since the advent of CT. In the early stages of cerebritis or with multiple abscesses, antibiotics may be used alone. An encapsulated abscess, particularly if the lesion is causing a mass effect or increased intracranial pressure, should be treated by a combination of antibiotics and aspiration. Surgical excision of an abscess is rarely required, because the procedure may be associated with greater morbidity compared with aspiration of a cavity. Surgery is indicated when the abscess is larger than 2.5?cm in diameter, gas is present in the abscess, the lesion is multiloculated, the lesion is located in the posterior fossa, or a fungus is identified. Associated infectious processes, such as mastoiditis, sinusitis, or a periorbital abscess, may require surgical drainage. The duration of antibiotic therapy depends on the organism and response to treatment, but it is usually is 4–6 wk.

Prognosis.

Mortality rate associated with brain abscess has decreased significantly, to approximately 5–10% with the use of CT or MRI and prompt antibiotic and surgical management. Factors associated with high mortality rate at the time of admission include multiple abscesses, coma, and lack of CT facilities. Long-term sequelae occur in at least 50% of survivors and include hemiparesis, seizures, hydrocephalus, cranial nerve abnormalities, and behavior and learning problems.

Chapter 596 - Pseudotumor Cerebri

Robert H. A. Haslam

Pseudotumor cerebri is a clinical syndrome that mimics brain tumors and is characterized by increased intracranial pressure (ICP) with a normal cerebrospinal fluid (CSF) cell count and protein content and normal ventricular size, anatomy, and position.

Etiology.

There are many explanations for the development of pseudotumor cerebri, including alterations in CSF absorption and production, cerebral edema, abnormalities in vasomotor control and cerebral blood flow, and venous obstruction. The causes of pseudotumor are numerous and include *metabolic disorders* (galactosemia, hypoparathyroidism, pseudohypoparathyroidism, hypophosphatasia, prolonged corticosteroid therapy or too rapid corticosteroid withdrawal, possibly growth hormone treatment, refeeding of a significantly malnourished child, hypervitaminosis A, vitamin A deficiency, Addison disease, obesity, menarche, oral contraceptives, and pregnancy), *infections* (roseola infantum, chronic otitis media and mastoiditis, Guillain-Barré syndrome), *drugs* (nalidixic acid, tetracycline, nitrofurantoin, isotretinoin), *hematologic disorders* (polycythemia, hemolytic and iron-deficiency anemia, Wiskott-Aldrich syndrome), *obstruction of intracranial drainage by venous thrombosis* (lateral sinus or posterior sagittal sinus thrombosis), head injury, and obstruction of the superior vena cava.

Clinical Manifestations.

The most frequent symptom is headache, and although vomiting also occurs, it is rarely as persistent and pernicious as that associated with a posterior fossa tumor. Diplopia secondary to paralysis of the abducens nerve is a frequent complaint. Most patients are alert and lack constitutional symptoms. Examination of the infant characteristically reveals a bulging fontanel and a “cracked-pot sound” or Macewen sign (percussion of the skull produces a resonant sound) due to separation of the cranial sutures. Papilledema with an enlarged blind spot is the most consistent sign

in a child beyond infancy. Early optic nerve edema may be noted with ultrasonography. An inferior nasal defect may be detected on formal tangent screen testing. The presence of focal neurologic signs indicates a process other than pseudotumor cerebri.

Treatment.

The prime goal in management should be discovery and treatment of the underlying cause. Pseudotumor cerebri is mainly a self-limited condition, but optic atrophy and blindness are the most significant complications. Consideration should be given to treating sinus thrombosis with anticoagulation. For many patients, repeated follow-up and monitoring of the visual acuity are all that is required. Serial visual-evoked potentials are useful if the visual acuity cannot be reliably documented. For others, the initial lumbar tap that follows a CT or MRI scan is diagnostic and therapeutic. The spinal needle produces a small rent in the dura that allows CSF to escape the subarachnoid space, thus reducing the ICP. Several additional lumbar taps and the removal of sufficient CSF to reduce the opening pressure by 50% occasionally lead to resolution of the process. Acetazolamide, 10–30?mg/kg/24?hr, and corticosteroids have been effective for some patients. Rarely, a lumboperitoneal shunt or subtemporal decompression is necessary if the aforementioned approaches are unsuccessful and optic nerve atrophy supervenes. Some centers perform optic nerve sheath fenestration. Finally, any patient whose increased ICP proves to be refractory to treatment warrants consideration for repeat neuroradiologic studies. A slow-growing tumor or obstruction of a venous sinus may become evident at the time of reinvestigation.

Chapter 597 - Spinal Cord Disorders

Robert H. A. Haslam

597.1 Spinal Cord Tumors

In children, spinal cord tumors account for approximately 20% of neuraxial tumors and are classified according to anatomic position (Fig. 597–1). *Intramedullary tumors* arise within the substance of the cord and grow slowly by infiltration, usually in the cervical region. The most common intramedullary tumor is a low-grade astrocytoma, followed by an ependymoma. *Extramedullary intradural tumors* tend to be benign and arise from neural crest tissue. Tumors in this area include neurofibroma, ganglioneuroma, and meningioma. *Extramedullary extradural tumors* characteristically

Figure 597.1-1 Diagram of the location of spinal cord tumors in children.

are metastatic lesions, particularly neuroblastoma, sarcoma, and lymphoma.

Clinical Manifestations.

Most children with spinal cord tumors present with a combination of gait disturbance, scoliosis, and back pain, depending on tumor location. Intramedullary gliomas are slow growing. Progressive difficulties in locomotion and sphincter disturbances are the earliest symptoms. Glial tumors in the cervical cord produce lower motor neuron signs in the upper extremities and upper motor neuron signs in the legs. Denervation of the intercostal muscles decreases chest wall movement and results in a weak cough. Loss of pain, temperature, and light touch sensation is evident in the lower extremities, and a cord level on occasion may be documented by light touch and pain sensation or by somatosensory-evoked potentials. With extramedullary tumors, the presenting symptom is often back pain. The child has difficulty sleeping because of pain and maintains a tripod posture while attempting to assume the supine position. If the tumor is attached to a nerve root, segmental pain, paresthesia, and weakness are evident. Extramedullary extradural tumors have a propensity to cause an acute block of the cerebrospinal fluid (CSF) pathways owing to rapid growth within a confined space. Such children present with a flaccid paraplegia, urinary retention, and a patulous anus. Some extramedullary tumors produce the Brown-Séquard syndrome, which consists of ipsilateral weakness, spasticity, and

ataxia, with contralateral loss of pain and temperature sensation. Papilledema is observed in a few patients, usually in association with markedly elevated CSF protein levels that presumably interfere with normal CSF flow dynamics.

Diagnosis.

It is important to establish the diagnosis of a spinal cord tumor as early as possible, because surgical management is facilitated and irreversible damage to the cord may be prevented. In approximately 40% of the cases, routine roentgenograms show abnormalities including widening of the interpediculate distance, destruction or sclerosis of the adjacent vertebral bodies or pedicles, and widening of the vertebral the foramen on an oblique view in the case of a neurofibroma or ganglioneuroma. MRI is the most important diagnostic test to establish the diagnosis. Intramedullary tumors produce a fusiform swelling of the cord, often with a complete block of the CSF (Fig. 597–2). Neurofibromas tend to create a circular indentation of the cord, and extramedullary tumors show various degrees of blockage.

Treatment.

With modern surgical techniques, many tumors can be totally and safely resected. Surgical removal of benign extramedullary tumors is associated with a good prognosis. For children with a primary neuroblastoma presenting with a sudden onset of paraplegia secondary to metastases in the extradural space, immediate radiation therapy may circumvent the need for a laminectomy.

597.2 Spinal Cord Trauma

(See also Chapters 51 and 88.3 .)

Acute spinal cord injuries in children may result from indirect trauma caused by hyperflexion, hyperextension, or vertical compression accidents; however, fracture dislocation of the vertebral column or epidural bleeding may also compromise spinal cord integrity secondary to a mass effect. As with the brain, the degree of injury to the spinal cord is variable and includes concussion, contusion, laceration, and transection. Recovery depends on the extent of the trauma as well as on the immediate and long-term management. Common causes of spinal cord injury include traumatic breech deliveries, physical abuse (as in the shaken baby syndrome), automobile and diving accidents, falls from playground equipment, and congenital defects such as the underlying vertebral abnormality in Down syndrome (DS).

Individuals with DS are susceptible to atlantoaxial instability resulting from laxity of the transverse ligaments. Atlantoaxial instability has been defined as a distance greater than 4.5?mm between the odontoid process of the axis and the anterior arch of the atlas. Spinal cord compression (myelopathy) may be a consequence of atlantoaxial instability. There is no consensus about the usefulness of radiograph screening in predicting spinal cord injury in children with DS. It is recommended that (1) lateral roentgenograms of the neck in the flexion position be obtained at 5–8 yr, 10–12 yr, and 18 yr in individuals with DS, because atlantoaxial instability can develop during periods of growth; (2) children with atlantoaxial instability be advised not

Figure 597.2-2 T1 weighted MRI scan of a spinal cord tumor (*white arrow*). The fusiform expansion of the cervical cord enhances following intravenous gadolinium injection.

to participate in risky sports, such as tumbling, diving, and football; (3) radiographs of the neck be obtained before operative procedures or therapeutic programs that involve active neck movement or manipulation; (4) parents and physicians be made aware of the symptoms and signs of cord compression (neck pain, urinary and fecal incontinence, head tilt, gait abnormalities, ataxia, hyperreflexia, weakness, spasticity, and quadriplegia); and (5) there be prompt investigation (neck radiographs, CT scan, MRI study) followed by consideration for operative intervention in patients with signs of myelopathy.

A patient with *severe cord injury* presents with **spinal shock**, consisting of flaccidity, areflexia, and loss of sensation. This may persist for up to 4 wk and results from dysfunction of synaptic activity in the pathways caudal to the injury. Ultimately, reflex flexor movements develop, followed by extensor reflex activity associated with

hyperactive deep tendon reflexes, spasticity, and an automatic bladder. *Fracture dislocations at the C5-C6 level* are the most common acute cause of spinal cord injuries and are characterized by a flaccid quadriparesis, loss of sphincter function, and a sensory level corresponding to the upper sternum. A transverse injury in the high cervical cord level (C1-C2) causes respiratory arrest and death in the absence of ventilatory support. Fractures in the low thoracic (T12-L1) region may produce the **conus medullaris syndrome,** which includes a loss of urinary and rectal sphincter control, flaccid weakness, and sensory disturbances of the legs. Spinal cord injury may occur in the absence of a vertebral fracture. A **central cord lesion** may result from contusion and hemorrhage and typically involves the upper extremities to a greater degree than the legs. There are lower motor neuron signs in the upper extremities and upper motor neuron signs in the legs, bladder dysfunction, and loss of sensation caudal to the lesion. Recovery may be considerable, particularly in the lower extremities.

Spinal cord injuries should be managed by stabilization and immobilization of the spine at the accident site using a cervical collar or sandbags. An adequate airway should be maintained, respiratory support should be provided, and shock should be treated with appropriate volume expanders. High-dose intravenous methylprednisolone (30?mg/kg bolus followed by 5.4?mg/kg/hr for 24?hr) should be started immediately, even before transport. If steroids are started within 3–8?hr of the injury, they should be continued for 48?hr. After transportation, roentgenograms of the spine, including oblique views, should be obtained. Approximately 50% of children with severe cord injuries show no abnormality on the spine roentgenogram. Fracture dislocations are treated with traction, immobilization, and, if the injury is unstable, vertebral fusion. Laminectomy and inspection of the cord are reserved for patients with progression of neurologic signs and appearance on CT or MRI scan that suggests an epidural or intraspinal hemorrhage. Additional therapeutic measures include management of bladder and gastrointestinal disturbances, nutritional and skin care, and a rigorous multidisciplinary rehabilitation program. The prognosis following spinal cord trauma is directly related to the extent of the injury. Recovery may occur over an extended period of months to years. Central cord injuries have a better prognosis than those injuries producing transverse lesions.

597.3 Tethered Cord

During fetal development, the spinal cord occupies the entire length of the vertebral column, but due to differential growth, the conus medullaris in a child ultimately assumes a position at the level of L1. Normal regression of the distal embryonic spinal cord produces a slender, threadlike filum terminale that is attached to the coccyx. A tethered cord results when a thickened ropelike filum terminale persists and anchors the conus at or below the L2 level. Neurologic signs may develop as a result of abnormal tension on the spinal cord, compromising blood

supply, particularly during flexion and extension movements. Diastematomyelia may coexist with a tethered cord. Inspection of the back shows a midline skin lesion in approximately 70% of cases, such as a lipoma, cutaneous hemangioma, tuft of hair, hyperpigmentation, or dermal pit. The clinical presentation varies, and signs may be evident at birth or may be delayed until adulthood. Infants may have asymmetric growth in a foot or leg associated with talipes cavus deformities and muscle wasting due to prolonged denervation. Abnormalities in bladder function with overflow incontinence, progressive scoliosis, and diffuse pain in the lower extremities are more common findings in a child. Plain roentgenograms of the lumbosacral spine demonstrate spina bifida in most cases. MRI precisely outlines the level of the conus medullaris and the filum terminale. Surgical transection of the thickened filum terminale tends to halt progression of neurologic signs and prevents the development of dysfunction in asymptomatic patients.

597.4 Diastematomyelia

Diastematomyelia is division of the spinal cord into two halves by projection of a fibrocartilaginous or bony septum originating from the posterior vertebral body and extending posteriorly. It represents a disorder of neural tube fusion with the persistence of mesodermal tissue from the primitive neurenteric canal acting as the septum. The defect involves the lumbar vertebrae (L1-L3) in approximately 50% of cases and tends to be associated with abnormalities of the vertebral bodies, including fusion defects, hemivertebra, hypoplasia, kyphoscoliosis, spina bifida, and myelomeningocele. A midline abnormality of the skin, such as a cutaneous hemangioma, provides a clue to the possibility of an underlying abnormality. The neurologic signs are thought to result from flexion and extension movements of the cord, which produce traction and additional trauma by the impaling septum. The clinical presentation of diastematomyelia varies, and in some cases patients may remain asymptomatic. Most often, unilateral foot abnormalities, including talipes equinovarus, claw toes, atrophy of the gastrocnemius, and loss of pain and temperature sensation, are apparent in a preschool child. A more progressive course may ensue, characterized by bilateral weakness and muscle atrophy in the lower extremities, absent ankle jerks, urinary incontinence, and low back pain. Plain roentgenograms of the vertebrae may not detect the septum due to lack of calcification; thus, CT scanning or MRI is the study of choice. The treatment of symptomatic patients is excision of the bony spur or septum and lysis of the adjacent adhesions.

597.5 Syringomyelia

Syringomyelia is a cystic cavity within the spinal cord that may communicate with the CSF pathways or remain localized and noncommunicating. *Syringobulbia* exists when the cystic cavity extends into the medulla. Although the pathogenesis of communicating syringomyelia is unknown, the prevailing hypothesis suggests a constriction of the central canal at the level of the foramen magnum during embryogenesis. CSF may pass caudad through the narrowed canal, especially during periods of increased intracranial pressure (e.g., sneezing, coughing), and produce dilatation of the central canal. Because of the constriction, CSF is prevented from flowing in a cephalic direction. Communicating syringomyelia is frequently associated with the Chiari type I malformation, whereas the noncommunicating syrinx is associated with cord tumors, vascular accidents, trauma, and arachnoiditis. Because of its slow evolution, syringomyelia rarely produces symptoms during childhood.

Interruption of the anterior white commissure at the level of the cervical cord disrupts the lateral spinothalamic tracts, causing an asymmetric loss of pain and temperature sensation in the upper extremities, with preservation of light touch (dissociation of sensation). Progressive enlargement of the cavity impinges on the anterior horn cells and corticospinal tracts, resulting in muscle wasting of the hands, absent deep tendon reflexes in the upper extremities, and upper motor neuron signs in the lower extremities. A rapidly progressive scoliosis may be the initial manifestation of syringomyelia. Trophic ulcers associated with vasomotor disturbances of the hands and arms indicate the loss of appreciation of pain. CT scanning with intrathecal injection of metrizamide outlines an enlarged spinal cord in the region of the syrinx, and a delayed scan displays the contrast medium within the cavity. MRI is the study of choice (Fig. 597–3). The management is surgical and depends on the site and cause of the syringomyelia. Decompression of the foramen magnum and the upper cervical vertebrae is recommended when the syrinx is associated with a Chiari type I or II anomaly. Additional procedures include insertion of a tissue plug in the open end of the central canal, draining the cystic cavity into the subarachnoid space, and percutaneous aspiration of the syrinx, which may result in marked improvement in neurologic function for prolonged periods.

597.6 Transverse Myelitis

Transverse myelitis is characterized by abrupt onset of progressive weakness and sensory disturbances in the lower extremities. A history of a preceding viral infection accompanied by fever and malaise is documented in most cases. Several viruses have been implicated, including Epstein-Barr virus and herpes, influenza, rubella, mumps, and varicella viruses. Additional infectious agents include Lyme disease and *Mycoplasma pneumoniae.* At least three hypotheses have been proposed to explain the pathogenesis of transverse myelitis: cell-mediated autoimmune response, direct viral invasion of the spinal cord, and autoimmune vasculitis. Pathologic examination of the cord

Figure 597.6-3 T1 weighted MRI scan of upper spinal cord showing an extensive syringomyelia (*white arrow*).

shows marked softening and perivascular cuffing by lymphocytes, supporting an immunologic basis for the disorder.

Low back or abdominal pain and paresthesias of the legs are prominent symptoms in the early stages. The leg muscles are weak and flaccid, and a sensory level is present, usually in the midthoracic region. Pain, temperature, and light touch sensation are affected, but joint position and vibration sense may be preserved. Sphincter disturbances are common, in which case catheterization of the bladder is necessary. Fever and nuchal rigidity are present early in most cases. The neurologic deficit evolves for 2–3 days and then plateaus, with flaccidity gradually changing to spasticity and with the concomitant development of upper motor neuron signs in the lower extremities. Examination of the CSF shows moderate lymphocyte pleocytosis and a normal or slightly elevated protein level. MRI is always indicated in a suspected case of transverse myelitis to rule out a compressive lesion compromising the cord. CT scanning or MRI reveals mild fusiform swelling in the affected region. Spontaneous recovery occurs over a period of weeks or months and is complete in approximately 60% of cases. Residual deficits include bowel and bladder dysfunction and weakness in the lower extremities. Management is directed to bladder care and physiotherapy. There is no evidence that steroids influence the course or the outcome of transverse myelitis. The differential diagnosis includes meningitis, infectious polyneuropathy (Guillain-Barré syndrome), poliomyelitis, neuromyelitis optica (Devic disease), spinal cord neoplasm, epidural abscess, and a vascular

malformation.

597.7 Arteriovenous Malformation

An arteriovenous malformation of the spinal cord consists of a collection of tortuous dilated veins that are usually located on the dorsal aspect of the thoracic cord. The malformation may cause neurologic symptoms by its mass effect on the cord or by the “steal” phenomenon, by which blood is shunted through the abnormal veins, bypassing the spinal cord, which produces transient and in some cases progressive loss of neurologic function. Patients occasionally present with acute paraparesis and a sensory deficit due to a subarachnoid bleed from the malformation. More commonly, gradual onset of gait abnormalities, low back pain, and bowel and bladder dysfunction are noted. The deep tendon reflexes are absent or reduced in the lower extremities, and the Babinski reflex is present. In approximately one third of cases, a midline cutaneous angioma overlies the arteriovenous malformation, and a spinal bruit may occasionally be auscultated. Roentgenograms of the spine may show erosion of the pedicles; however, contrast myelography and selective spinal angiography are required to delineate the blood supply and the extent of the malformation. The malformation is removed by surgical excision with the use of an operating microscope or is obliterated by embolization.

Part 27 - Neuromuscular Disorders

Harvey B. Sarnat

The term *neuromuscular disease* defines disorders of the motor unit and excludes influences on muscle function from the brain, such as in spasticity. The motor unit has four components: (1) a motor neuron in the brainstem or ventral horn of the spinal cord; (2) its axon that, together with other axons, forms the peripheral nerve; (3) the neuromuscular junction; and (4) all muscle fibers innervated by a single motor neuron. The size of the motor unit varies among different muscles and with the precision of muscular function required. In large muscles, such as the glutei and quadriceps femoris, hundreds of muscle fibers are innervated by a single motor neuron; in small finely tuned muscles, such as the stapedius or the extraocular muscles, a 1:1 ratio may prevail. The motor unit is influenced by suprasegmental or upper motor neuron control that alters properties of muscle tone, precision of movement, reciprocal inhibition of antagonistic muscles during movement, and sequencing of muscle contractions to achieve smooth, coordinated movements. Suprasegmental impulses also augment or inhibit the monosynaptic stretch reflex; the corticospinal tract is inhibitory upon this reflex.

Diseases of the motor unit are common in children. These neuromuscular diseases may or may not be genetically determined, congenital or acquired, acute or chronic, and progressive or static. Because specific therapy is available for many diseases and because of genetic and prognostic implications, precise diagnosis is important; laboratory confirmation is required for most diseases because of overlapping clinical manifestations.

Many chromosomal loci have been identified with specific neuromuscular diseases as a result of genetic linkage studies and the isolation and cloning of a few specific genes. In some cases, such as Duchenne muscular dystrophy, the genetic defect has been shown to be a deletion of nucleotide sequences and is associated with a defective protein product, dystrophin; in other cases, such as myotonic muscular dystrophy, the genetic defect is an expansion or repetition, rather than a deletion, in a codon (a set of three consecutive nucleotide repeats that encodes for a single amino acid), with many copies of a particular codon, in this example also associated with abnormal mRNA. Some diseases present as autosomal dominant and autosomal recessive traits in different pedigrees; these distinct mendelian genotypes may result from different genetic mutations on different chromosomes (e.g., nemaline rod myopathy) or may be small differences in the same gene at the same

chromosomal locus (e.g., myotonia congenita), despite many common phenotypic features and shared histopathologic findings in a muscle biopsy specimen. Among the several clinically defined mitochondrial myopathies, specific mtDNA deletions and tRNA point mutations are recognized. The inheritance patterns and chromosomal and mitochondrial loci of common neuromuscular diseases affecting infants and children are summarized in Table 599–1 .

Chapter 598 - Evaluation and Investigation

Clinical Manifestations.

Examination of the neuromuscular system includes an assessment of muscle bulk, tone, and strength. Tone and strength should not be confused: Passive tone is range of motion around a joint; active tone is physiologic resistance to movement. Head lag when an infant is pulled to a sitting position from supine is a sign of weakness, not of low tone. Hypotonia may be associated with normal strength or with weakness; enlarged muscles may be weak or strong; thin, wasted muscles may be weak or have unexpectedly normal strength. The distribution of these components is of diagnostic importance. In general, myopathies follow a proximal distribution of weakness and muscle wasting (with the notable exception of myotonic muscular dystrophy); neuropathies are generally distal in distribution (with the notable exception of juvenile spinal muscular atrophy). Involvement of the face, tongue, palate, and extraocular muscles provides an important distinction in the differential diagnosis. Tendon stretch reflexes are generally lost in neuropathies and in motor neuron diseases and are diminished but preserved in myopathies. A few specific clinical features are important in the diagnosis of some neuromuscular diseases. Fasciculations of muscle, which are often best seen in the tongue, are a sign of denervation. Sensory abnormalities indicate neuropathy. Fatigable weakness is characteristic of neuromuscular junctional disorders. Myotonia is specific for a few myopathies.

Some features do not distinguish myopathy from neuropathy. Muscle pain or myalgias are associated with acute disease of either myopathic or neurogenic origin. Both acute dermatomyositis and acute polyneuropathy (Guillain-Barré syndrome) are characterized by myalgias. Muscular dystrophies and spinal muscular atrophies are not associated with muscle pain. Myalgias also occur in several metabolic diseases of muscle and in ischemic myopathy. Contractures of muscles, whether present at birth or developing later in the course of an illness, occur in both myopathic and neurogenic diseases.

Infant boys who are weak in late fetal life and in the neonatal period often have undescended testes. The testes are actively pulled into the scrotum from the anterior abdominal wall by a pair of cords that consist of smooth and striated muscle called the gubernaculum (Fig. 598–1). The gubernaculum is weakened in many congenital neuromuscular diseases, including spinal muscular atrophy, myotonic muscular dystrophy, and many congenital myopathies.

The thorax of infants with congenital neuromuscular disease often has a funnel shape, and the ribs are thin and radiolucent, owing to intercostal muscle weakness during intrauterine growth. This phenomenon is characteristically found in infantile spinal muscular atrophy but also occurs in myotubular myopathy, neonatal myotonic dystrophy, and other disorders. Because of the small muscle mass, birth weight may be low for gestational age.

Generalized hypotonia and motor developmental delay are the most common presenting manifestations of neuromuscular disease in infants and young children. These features may also be expressions of neurologic disease, endocrine and systemic metabolic diseases, and Down syndrome, or they may be nonspecific neuromuscular expressions of malnutrition or chronic systemic illness. A prenatal history of decreased fetal movements and intrauterine growth retardation is often found in patients who are symptomatic at birth.

Laboratory Findings

SERUM ENZYMES.

Several lysosomal enzymes are released by damaged or degenerating muscle fibers and may be measured in serum. The most useful of these enzymes is the *creatine kinase* (CK), which is found in only three organs and may be separated into corresponding isozymes: MM for skeletal muscle, MB for cardiac muscle, and BB for brain. Serum CK determination is by no means a universal screening test for neuromuscular disease because many diseases of the motor unit may not be associated with elevated enzymes. However, the CK level is characteristically elevated in certain diseases, such as Duchenne

Figure 598-1 Undescended testes are common in male neonates with neuromuscular disease already symptomatic at birth, regardless of the cause. The gubernaculum is a cylinder of striated muscle surrounding a core of smooth muscle that actively pulls the testis into the scrotum in late gestation. Weakness of the gubernaculum in a generalized myopathy of fetal life prevents or delays the descent of the testis. (Reproduced with permission from Sarnat HB, Sarnat MS: Disorders of muscle in the newborn. In Moss AJ, Stern L [editors]: *Pediatrics Update,* 4th ed. New York, Elsevier-North Holland, 1983.)

muscular dystrophy, and the magnitude of increase is characteristic for particular diseases.

MOLECULAR GENETIC MARKERS.

Many DNA markers of hereditary myopathies and neuropathies are now available from blood samples. If the clinical manifestations cause suspicion of a particular disease, these tests may provide a definitive diagnosis and not subject the child to more invasive procedures, such as muscle biopsy. Other molecular markers are available only in muscle biopsy tissue. Genetic blood tests, whether ordered

individually or in “panels,” are expensive and often are excluded in health insurance plans.

NERVE CONDUCTION VELOCITY (NCV).

Motor and sensory nerve conduction may be measured electrophysiologically by using surface electrodes. Neuropathies of various types are detected by decreased conduction. The site of a traumatic nerve injury may also be localized. The nerve conduction at birth is about half of the mature value achieved by age 2 yr. Tables are available for normal values at various ages in infancy, including for preterm infants. Because the NCV study measures only the fastest conducting fibers in a nerve, 80% of the total nerve fibers must be involved before slowing in conduction is detected.

ELECTROMYOGRAPHY (EMG).

EMG requires insertion of a needle into the belly of a muscle and recording the electric potentials in various states of contraction. It is less useful in pediatrics than in adult medicine, in part because of technical difficulties in recording these potentials in young children and in part because the best results require the patient's cooperation for full relaxation and maximal voluntary contraction of a muscle. Most children are too frightened to provide such cooperation. Characteristic EMG patterns distinguish denervation from myopathic involvement. The specific type of myopathy is not usually definitively diagnosed, but certain specialized myopathic conditions, such as myotonia, may be demonstrated. An EMG may transiently raise the serum CK level.

EMG combined with repetitive electrical stimulation of a motor nerve supplying a muscle to produce tetany is useful in demonstrating myasthenic decremental responses. Small muscles, such as the abductor digiti quinti of the hypothenar eminence, are used for such studies.

MUSCLE BIOPSY.

The muscle biopsy is the most important and specific diagnostic study of most neuromuscular disorders, if the definitive diagnosis of a hereditary disease is not provided by molecular genetic testing in blood. Not only are neurogenic and myopathic processes distinguished, but also the type of myopathy and specific enzymatic deficiencies may be determined. The vastus lateralis (quadriceps femoris) is the muscle that is most commonly sampled. The deltoid muscle should be avoided in most cases because it normally has a 60–80% predominance of type I fibers so that the distribution patterns of fiber types are difficult to recognize. Muscle biopsy is a simple outpatient procedure that may be performed under local anesthesia with or without femoral nerve block. Needle biopsies are not recommended because they require an incision in the skin similar to open biopsy, numerous samples must be taken to conduct an adequate examination of the tissue, and they provide inferior specimens.

Histochemical studies of frozen sections of the muscle are obligatory in all pediatric muscle biopsies because many congenital and metabolic myopathies cannot be diagnosed from paraffin sections using conventional histologic stains. Immunohistochemistry is a useful supplement in some cases, such as for demonstrating dystrophin in suspected Duchenne muscular dystrophy or merosin in congenital muscular dystrophy. A portion of the biopsy specimen should be fixed for potential electron microscopy, but ultrastructure has additional diagnostic value only in selected cases. Muscle biopsy sample interpretation is complex and should be performed by an experienced pathologist. A portion of frozen muscle tissue should also be routinely saved for possible biochemical analysis (e.g., mitochondrial cytopathies, carnitine palmityltransferase, acid maltase).

NERVE BIOPSY.

The most commonly sampled nerve is the sural nerve, which is a pure sensory nerve that supplies a small area of skin on the lateral surface of the foot. Whole or fascicular biopsy specimens of this nerve may be taken. When the sural nerve is severed behind the lateral malleolus of the ankle, regeneration of the nerve occurs in more than 90% of cases so that permanent sensory loss is not experienced. The sural nerve is often involved in many neuropathies whose clinical manifestations are predominantly motor.

Electron microscopy is performed on most nerve biopsy specimens because many morphologic alterations cannot be appreciated at the resolution of a light microscope. Teased fiber preparations are sometimes useful in demonstrating segmental demyelination, axonal swellings, and other specific abnormalities, but this time-consuming procedure is not done routinely. Special stains may be applied to ordinary frozen or paraffin sections of nerve biopsy material to demonstrate myelin, axoplasm, and metabolic products.

ELECTROCARDIOGRAPHY (ECG).

Cardiac evaluation is important if myopathy is suspected because of involvement of the heart in muscular dystrophies and in inflammatory and

metabolic myopathies. ECG often detects early cardiomyopathy or conduction defects that are clinically asymptomatic. At times, a more complete cardiac work-up, such as echocardiography and consultation with a pediatric cardiologist, may be indicated. Serial pulmonary function tests also should be performed in muscular dystrophies and in other chronic or progressive diseases of the motor unit.

Chapter 599 - Developmental Disorders of Muscle

A heterogeneous group of congenital neuromuscular disorders is sometimes known as the *congenital myopathies*, but in some of these disorders the assumption that the pathogenesis is primarily myopathic is unjustified. Most congenital myopathies are nonprogressive conditions, but some patients show slow clinical deterioration accompanied by additional changes in their muscle biopsy specimen. Most of the diseases in the category of congenital myopathies are hereditary; others are sporadic. Although clinical features, including phenotype, may raise a strong suspicion of a congenital myopathy, the definitive diagnosis is determined by the histopathologic findings in the muscle biopsy specimen. In conditions for which the defective gene has been identified, the diagnosis may be established by the specific molecular genetic probe on lymphocytes. The morphologic and histochemical abnormalities differ considerably from those of the muscular dystrophies, spinal muscular atrophies, and neuropathies. Many are reminiscent of the embryologic development of muscle, thus suggesting possible defects in the genetic regulation of muscle development.

Myogenic Regulatory Genes and Genetic Loci of Inherited Diseases of Muscle (Table 599–1).

A family of four myogenic regulatory genes shares encoding transcription factors of “basic helix-loop-helix” (bHLH) proteins associated with common DNA nucleotide sequences. These proto-oncogenes direct the differentiation of striated muscle from any undifferentiated mesodermal cell; some are so strongly expressed that they convert partially differentiated mesenchymal cells, such as fibroblasts or chondroblasts, into myoblasts. The earliest bHLH gene to program the differentiation of myoblasts is myogenic factor 5 *(Myf5)*. The second gene, *myogenin*, promotes fusion of myoblasts to form myotubes. *Herculin* (also known as *MYF6*) and *MYOD1* are the other two myogenic genes. *Myf5 cannot support myogenic differentiation without myogenin*, *MyoD,* and *MYF6*. Each of these four genes can activate the expression of at least one other and, under certain circumstances, can autoactivate as well. The expression of *MYF5* and of *herculin* is transient in early ontogenesis but returns later in fetal life and persists into adult life. The human locus of the *MYOD1* gene is on chromosome 11, very near to the domain associated with embryonal rhabdomyosarcoma. The genes encoding *Myf5* and *herculin* are on chromosome 12 and that for *myogenin* is on chromosome 1. The myogenic genes are activated during muscle regeneration, recapitulating the developmental process; *MyoD* in particular is required for myogenic stem cell (i.e., satellite cell) activation in

TABLE 599-1 -- Inheritance Patterns and Chromosomal or Mitochondrial Loci of Neuromuscular Diseases Affecting the Pediatric Age Group

Disease	Transmission	Locus
Duchenne/Becker muscular dystrophy	XR	Xp21.2
Emery-Dreifuss muscular dystrophy	XR	Xq28
Myotonic muscular dystrophy (Steinert)	AD	19q13
Facio-scapulo-humeral muscular dystrophy	AD	4q35

Mitochondrial myopathy (MERRF)	Maternal	tRNA point mutation at position 8344
Mitochondrial myopathy (MELAS)	Maternal	tRNA point mutation at positions 3243 and 3271

AD = autosomal dominant; AR = autosomal recessive; XR = X-linked recessive; MERRF = mitochondrial encephalomyopathy with ragged-red fibers; MELAS = mitochondrial encephalomyopathy with lactic acidosis and strokelike episodes; mtDNA = mitochondrial deoxyribonucleic acid; tRNA = transfer ribonucleic acid.

adult muscle. The *PAX3* gene also plays an important role in myogenesis and interacts with each of the four basic genes mentioned above. Another gene, *myostatin*, is a negative regulator of muscle development by preventing myocytes from differentiating. The precise role of the myogenic genes in developmental myopathies is not yet defined.

599.1 Myotubular Myopathy

The term *myotubular myopathy* implies a maturational arrest of fetal muscle during the myotubular stage of development at 8–15 wk of gestation. It is based on the morphologic appearance of myofibers: A row of central nuclei lie within a core of cytoplasm; contractile myofibrils form a cylinder around this core (Fig. 599–1). Many challenge this interpretation and use the more neutral term *centronuclear myopathy* when referring to this myopathy. But this term is too nonspecific because internal nuclei occur in many unrelated myopathies.

Pathogenesis.

Although the pathogenesis has sometimes been suggested to be neurogenic, spinal motor neurons are normal in number and morphology. Peripheral nerves also usually have normal ultrastructure and conduction velocity. Persistently high fetal concentrations of vimentin and desmin are demonstrated in myofibers of infants with myotubular myopathy, although not reproduced in cultured myocytes of patients. These intermediate filament proteins serve as cytoskeletal elements in fetal myotubes, attaching nuclei and mitochondria to the sarcolemmal membranes to preserve their central positions. As intracellular organization changes with maturation, the nuclei move to the periphery and mitochondria are redistributed between myofibrils. At the same time, vimentin and desmin diminish. Vimentin disappears altogether by term, and desmin remains

Figure 599.1-1 *A*, Cross-section of muscle from a 14-wk-old human fetus; *B*, normal full-term neonate; and *C*, term neonate with X-linked recessive myotubular myopathy. Myofibers have large central nuclei in the fetus and in myotubular myopathy, and nuclei are at the periphery of the muscle fiber in the term neonate as in the adult. (Hematoxylin & eosin, ×500.)

only in trace amounts. Persistent fetal vimentin and desmin in muscle fibers may be one mechanism of “maturational arrest.” A secondary myasthenia-like defect in neuromuscular transmission also occurs in some infants with myotubular myopathy. Myocytes of patients co-cultured with nerve in vitro develop normal innervation and mature normally, not reproducing the in vivo pathologic changes.

Clinical Manifestations.

Decreased fetal movements may occur in late gestation. Polyhydramnios is a common complication because of pharyngeal weakness of the fetus and inability to swallow amniotic fluid. At birth, affected infants have a thin muscle mass involving axial, limb girdle, and distal muscles; severe generalized hypotonia; and diffuse weakness. Respiratory efforts may be ineffective, requiring ventilatory support. Gavage feeding may be required because of weakness of the muscles of sucking and deglutition. The testes are often undescended. Facial muscles may be weak, but infants do not have the characteristic facies of myotonic dystrophy. Ophthalmoplegia is observed in a few cases. The palate may be high. The tongue is thin, but fasciculations are not seen. Tendon stretch reflexes are weak or absent. Myotubular myopathy is not associated with cardiomyopathy; mature cardiac muscle fibers normally have central nuclei. Congenital anomalies of the central nervous system or of other systems are not associated.

Older children and adults may develop centronuclear myopathy with variable weakness. The relation of this disorder to the severe neonatal disease is uncertain.

Laboratory Findings.

Serum levels of creatine phosphokinase (CK) are normal. The electromyogram (EMG) does not show evidence of denervation; results are usually normal or show minimal nonspecific myopathic features in early infancy. Nerve conduction velocity may be slow but is usually normal. The electrocardiogram (ECG) appears normal. Roentgenograms of the chest show no cardiomegaly; the ribs may be thin.

Diagnosis.

The muscle biopsy findings are diagnostic at birth, even in premature infants. More than 90% of muscle fibers are small and have centrally placed, large vesicular nuclei in a single row. Spaces between nuclei are filled with sarcoplasm containing mitochondria. Histochemical stains for oxidative enzymatic activity and glycogen reveal a central distribution as in fetal myotubes. The cylinder of myofibrils shows mature histochemical differentiation with adenosine triphosphatase (ATPase) stains. The connective tissue of muscle, spindles, blood vessels, intramuscular nerves, and motor end plates are mature. Ultrastructural features in neonatal myotubular myopathy, other than those that define the disease, are also mature. Vimentin and desmin show strong immunoreactivity in muscle fibers in myotubular myopathy and no demonstrable activity in normal term neonatal muscle. The molecular genetic marker in blood is available and is useful not only for confirming the diagnosis but also for early prenatal diagnosis.

Genetics.

X-linked recessive inheritance is the most common trait; most patients are boys. The mothers of affected infants are clinically asymptomatic, but their muscle biopsy specimen shows minor alterations. Autosomal dominant and autosomal recessive forms are also reported but are rarer.

Genetic linkage on the X chromosome has been localized to the Xq28 site, a locus different from the Xp21 gene of Duchenne and Becker muscular dystrophies. A deletion in the responsible *MTM1* gene has been identified. It encodes a protein, myotubularin, with a putative tyrosine phosphatase domain. Although only a single gene is involved, five distinct point mutations of the *MTM1* gene out of 242 known mutations account for only 27% of cases; many different alleles may produce the same clinical disease.

Treatment.

Only supportive and palliative treatment is available.

Prognosis.

About 75% of severely affected neonates die within the first few weeks or months of life. Survivors do not experience a progressive course but have major physical handicaps, rarely walk, and remain severely hypotonic.

599.2 Congenital Muscle Fiber-Type Disproportion (CMFTD)

This condition occurs as an isolated “congenital myopathy” but also develops in association with various unrelated disorders that include nemaline rod disease, Krabbe disease (globoid cell leukodystrophy) early in the course before expression of the neuropathy, cerebellar hypoplasia and certain other brain malformations (see later), fetal alcohol syndrome, some glycogenoses, multiple sulfatase deficiency, Lowe's syndrome, rigid spine myopathy, and some infantile cases of myotonic muscular dystrophy.

Pathogenesis.

The association of CMFTD with cerebellar hypoplasia (see later) suggests that the pathogenesis may be an abnormal suprasegmental influence on the developing motor unit during the stage of histochemical differentiation of muscle between 20 and 28 wk of gestation. Muscle fiber types and growth are determined by innervation and are mutable even in adults. Although CMFTD does not actually correspond with any normal stage of development, it appears to be an embryologic disturbance of fiber type differentiation and growth.

Clinical Manifestations.

As an isolated condition not associated with other diseases, CMFTD is a nonprogressive disorder present at birth. Patients have generalized hypotonia and weakness, but the weakness is usually not severe and respiratory distress and dysphagia are rare. Mild congenital contractures are often present. Poor head control and developmental delay for gross motor skills are common in infancy. Walking is usually delayed until 18–24 mo but is eventually achieved. Because of the hypotonia, subluxation of the hips may occur. Muscle bulk is reduced. The muscle wasting and hypotonia are proportionately greater than the weakness, and the child may be stronger than expected during examination. Cardiomyopathy is a rare complication.

The facies of children with CMFTD often raise suspicion, especially if the child is referred for assessment of developmental delay and hypotonia. The head is dolichocephalic, and facial weakness is present. The palate is usually high arched. Thin muscles of the trunk and extremities give a thin, wasted appearance. Patients do not complain of myalgias. The clinical course is benign and nonprogressive. The facies and body habitus of many children with CMFTD may be indistinguishable from those of nemaline rod myopathy (see later), which also includes CMFTD as a component.

Laboratory Findings.

Serum CK, ECG, EMG, and nerve conduction velocity results are normal in simple CMFTD. If other diseases are associated, laboratory investigation of those conditions discloses the specific features.

Diagnosis.

CMFTD is diagnosed by a muscle biopsy that shows a disproportion in both size and relative ratios of histochemical fiber types: Type I fibers are uniformly small, and type II fibers are hypertrophic; type I fibers are more numerous than those of type II. Degeneration of myofibers and other primary myopathic features are absent. The biopsy is diagnostic at birth.

Genetics.

Many cases of simple CMFTD are sporadic, although autosomal recessive inheritance is well documented in some families and an autosomal dominant trait is suspected in others. CMFTD also may be associated with cerebellar hypoplasia.

Treatment.

No drug therapy is available. Physiotherapy may be helpful for some patients in strengthening muscles that do not

receive sufficient exercise in daily activities. Mild congenital contractures often respond well to gentle range of motion exercises and rarely require plaster casting or surgery.

599.3 Nemaline Rod Myopathy

Nemaline rods (derived from the Greek *nema*, meaning “thread”) are rod-shaped inclusion-like abnormal structures within muscle fibers. They are difficult to demonstrate histologically with conventional hematoxylin-eosin stain but are easily seen with special stains. They are not foreign inclusion bodies but rather consist of excessive Z-band material with a similar ultrastructure (Fig. 599–2). Chemically, the rods are composed of actin, a-actinin, tropomyosin-3, and the protein nebulin. Nemaline rod formation may be an unusual reaction of muscle fibers to injury because these rod structures have rarely been found in other diseases. They are most abundant in the congenital myopathy known as nemaline rod disease. Most rods are within the myofibrils (cytoplasmic), but intranuclear rods are occasionally demonstrated by electron microscopy; how they form in the nucleus is unknown.

Clinical Manifestations.

Severe infantile and juvenile forms of the disease are known. Patients resemble those with CMFTD, except that they are more severely affected. Generalized hypotonia, weakness including bulbar-innervated and respiratory muscles, and a very thin muscle mass are characteristic (Fig. 599–3). The head is dolichocephalic, and the palate high arched or even cleft. Muscles of the jaw may be too weak to hold it closed (Fig. 599–4). Infants may be severely weak at birth; some die in the neonatal period. Decreased fetal movements are reported by the mother, and neonates suffer from hypoxia and dysphagia and sometimes have arthrogryposis.

Laboratory Findings.

Serum CK level is normal. The muscle biopsy sample shows CMFTD or at least fiber type I predominance in addition to the nemaline rods. In some patients, uniform type I fibers are seen with few or no type II fibers. Focal myofibrillar degeneration and an increase in lysosomal enzymes have been found in a few severe cases associated with progressive symptoms. Intranuclear nemaline rods correlate with the most severe clinical manifestations.

Genetic Aspects.

Autosomal dominant and autosomal recessive forms of nemaline rod disease occur, and an X-linked dominant form in girls also may occur. Autosomal dominant nemaline rod

Figure 599.3-2 Electron micrograph of the muscle from a patient shown in Figure 599–4 . Nemaline rods (nr) are seen within many myofibrils. They are identical in composition to the normal Z bands (z). (×6000.)

Figure 599.3-3 Back of a 13-yr-old girl with juvenile form of nemaline rod disease. The paraspinal muscles are very thin, and winging of the scapulae is evident. The muscle mass of the extremities is also greatly reduced both proximally and distally.

myopathy has been mapped to the 1q21-23 locus; the responsible gene, *TPM3*, programs tropomyosin-3, an important component of the Z band. The more common autosomal recessive form results from a defective gene at the 2q21.2-q22 locus that produces *nebulin*, a large molecule also needed for Z-band integrity.

Treatment and Prognosis.

Therapy is supportive. Survivors are confined to an electric wheelchair and are usually unable to overcome gravity. Both proximal and distal muscles are involved.

Figure 599.3-4 Infantile form of nemaline rod disease in a 6-yr-old boy. Facial weakness and generalized muscle wasting are severe. The head is dolichocephalic. The mouth is usually open because the masseters are too weak to lift the mandible against gravity for more than a few seconds.

Gastrostomy may be needed for chronic dysphagia. In the juvenile form, patients are ambulatory and are able to perform most tasks of daily living. Weakness is not usually progressive, but some patients have more difficulty over time or enter a phase of progressive weakness. Cardiomyopathy is an uncommon complication. Pneumonia occurs frequently.

599.4 Central Core Disease

This autosomal dominant disease, caused by an abnormal gene at the 19q13.1 locus, is characterized pathologically by central cores within muscle fibers in which only amorphous, granular cytoplasm is found with an absence of myofibrils and organelles. Histochemical stains show a lack of enzymatic activities of all types within these cores. Infantile hypotonia, proximal weakness, muscle wasting, and involvement of facial muscles and neck flexors are the typical features. The course is nonprogressive, and the weakness is not usually severely disabling. Congenital dislocated hips and skeletal deformities are common. Scoliosis occurs even without much axial weakness.

Central core disease is consistently associated with malignant hyperthermia, and all patients should have special precautions with pretreatment by dantrolene before an anesthetic agent is administered. The serum CK value is normal in central core disease except during crises of malignant hyperthermia. See Chapter 602.2 .

Variants of central cores, called *minicores* and *multicores*, are described in some families, but minicore myopathy is probably a different genetic disease. Children with this disorder are hypotonic in early infancy and have a benign course but often develop progressive kyphoscoliosis or a rigid spine in adolescence. Some children with Prader-Willi syndrome have focal loss of myofilaments resembling early central cores.

599.5 Brain Malformations and Muscle Development

Infants with *cerebellar hypoplasia* are hypotonic and developmentally delayed. Muscle biopsy is sometimes performed to exclude a congenital myopathy. A biopsy specimen may show delayed maturation of muscle, fiber-type predominance, or CMFTD. Other malformations of the brain may also be associated with abnormal histochemical patterns, but supratentorial lesions are less likely than brain stem or cerebellar lesions to alter muscle development. Abnormal descending impulses along bulbospinal pathways probably alter discharge patterns of lower motor neurons that determine the histochemical differentiation of muscle. The corticospinal tract does not participate because it is not yet functional during this period of fetal life.

599.6 Amyoplasia

Congenital absence of individual muscles is common and is often asymmetric. A common aplasia is the *palmaris longus muscle* of the ventral forearm, which is absent in 30% of normal subjects and is fully compensated by other flexors of the wrist. Unilateral absence of a *sternocleidomastoid muscle* is one cause of congenital torticollis. Absence of one *pectoralis major muscle* is part of the Poland anomalad.

When innervation does not develop, such as in the lower limbs in severe cases of *myelomeningocele*, muscles may fail to develop. In *sacral agenesis*, the abnormal somites that fail to form bony vertebrae may also fail to form muscles from the same defective mesodermal plate, a disorder of induction resulting in segmental amyoplasia. Skeletal muscles of the extremities fail to differentiate from embryonic myomeres if the long bones do not form. Absence of one long bone, such as the radius, is associated with variable aplasia or hypoplasia of associated muscles, such as the *carpi flexor radialis*. End-stage neurogenic atrophy of muscle is sometimes called *amyoplasia*, but this use is semantically incorrect.

Generalized amyoplasia usually results in fetal death, and live-born neonates rarely survive. A mutation in one of the myogenic genes is the suspected etiology because of genetic knockout studies in mice, but it has not been proven in humans.

599.7 Muscular Dysgenesis (Proteus Syndrome Myopathy)

The *Proteus syndrome* is a disturbance of cellular growth involving ectodermal and mesodermal tissues. The cause is unknown, but it is not a mendelian trait. It presents as asymmetric overgrowth of the extremities, verrucous cutaneous lesions, angiomas of various types, thickening of bones, hemimegalencephaly, and excessive growth of muscles without weakness. Histologically, the muscle is a unique *muscular dysgenesis*. Abnormal zones are adjacent to zones of normal muscle formation and do not follow anatomic boundaries. The disorder may be due to abnormal paracrine growth factors. Historically the “elephant man,” who was exploited for his grotesque features in late 19th century London and became a popular sensation, was long misdiagnosed as having neurofibromatosis but is now recognized to have had Proteus syndrome.

599.8 Benign Congenital Hypotonia

Benign congenital hypotonia is not a disease but is a descriptive term for infants or children with nonprogressive hypotonia of unknown origin. The hypotonia is not usually associated with weakness or developmental delay, although some children acquire gross motor skills more slowly than normal. Tendon stretch reflexes are normal or hypoactive. There are no cranial nerve abnormalities, and intelligence is normal.

The *diagnosis* is one of exclusion after results of laboratory studies, including muscle biopsy and imaging of the brain with special attention to the cerebellum, are normal. No known molecular genetic basis for this syndrome has been identified.

The *prognosis* is generally good; no specific therapy is required. Contractures do not develop. Hypotonia persists into adult life. The disorder is not always as “benign” as its name implies, because a common complication is recurrent dislocation of joints, especially the shoulders. Excessive motility of the spine may result in stretch injury, compression, or vascular compromise of nerve roots or of the spinal cord. These are particular hazards for patients who perform gymnastics or who become circus performers because of agility of joints without weakness or pain.

599.9 Arthrogryposis

Arthrogryposis multiplex congenita is not a disease but is a descriptive term that signifies numerous congenital contractures. The causes encompass both neurogenic and primary myopathic diseases, but most cases, and indeed the most severe cases, are not due to neuromuscular disease. Myopathies that have a high incidence of either minor congenital contractures or extensive arthrogryposis include myotonic muscular dystrophy, many congenital myopathies, and intrauterine viral myositis. Neurogenic diseases causing arthrogryposis include infantile spinal muscular atrophy and the Pena-Shokeir and Marden-Walker syndromes (see Chapter 672).

Chapter 600 - Muscular Dystrophies

The term *dystrophy* means abnormal growth, derived from the Greek *trophe*, meaning "nourishment." *Muscular dystrophy* implies much more than simply aberrant growth or nutrition of muscle fibers. A muscular dystrophy is distinguished from all other neuromuscular diseases by four obligatory criteria: (1) It is a primary myopathy; (2) it has a genetic basis; (3) the course is progressive; (4) degeneration and death of muscle fibers occur at some stage in the disease. This definition excludes neurogenic diseases such as spinal muscular atrophy, nonhereditary myopathies such as dermatomyositis, nonprogressive and non-necrotizing congenital myopathies such as congenital muscle fiber–type disproportion (CMFTD), and nonprogressive inherited metabolic myopathies. Some metabolic myopathies may fulfill the definition of a progressive muscular dystrophy but are not traditionally classified as dystrophies. An example is muscle carnitine deficiency. Conversely, all muscular dystrophies might eventually be reclassified as metabolic myopathies once the biochemical defects are better defined.

Muscular dystrophies are a group of unrelated diseases, each transmitted by a different genetic trait and each differing in its clinical course and expression. Some are severe diseases at birth or lead to early death; others follow very slow progressive courses over many decades, may be compatible with normal longevity, or may not even become symptomatic until late adult life. Some categories of dystrophies, such as limb-girdle muscular dystrophy, are not homogeneous diseases but rather syndromes encompassing several distinct myopathies. Relationships between the various muscular dystrophies are resolved by molecular genetics rather than by similarities or differences in clinical and histopathologic features.

600.1 Duchenne and Becker Muscular Dystrophies

Duchenne muscular dystrophy is the most common hereditary neuromuscular disease affecting all races and ethnic groups. Its incidence is 1:3,600 liveborn infant boys. This disease is inherited as an X-linked recessive trait. The abnormal gene is on the X chromosome at the Xp21 locus and is one of the largest genes identified. Becker muscular dystrophy is the same fundamental disease as Duchenne dystrophy, with a genetic defect at the same locus, but clinically it follows a milder and more protracted course.

Duchenne recognized most of the characteristic clinical features in 1861: hypertrophy of the calves, progressive weakness, intellectual impairment, and proliferation of connective tissue in muscle.

Clinical Manifestations.

Infant boys are only rarely symptomatic at birth or in early infancy, although some are already mildly hypotonic. Early gross motor skills, such as rolling over, sitting, and standing, are usually achieved at the appropriate ages or may be mildly delayed. Poor head control in infancy may be the first sign of weakness. Distinctive facies are not a feature because facial muscle weakness is a late event. Walking is often accomplished at the normal age of about 12 mo, but hip girdle weakness may be seen in subtle form as early as the 2nd year. Toddlers may assume a lordotic posture when standing to compensate for gluteal weakness. An early Gowers sign is often evident by age 3 yr and is fully expressed by age 5 or 6 yr (see Fig. 584–2). A Trendelenburg gait, or hip waddle, appears at this time.

The length of time that a patient remains ambulatory varies greatly. Some patients are confined to a wheelchair by 7 yr of age; most patients continue to walk with increasing difficulty until age 10 yr without orthopedic intervention. With orthotic bracing, physiotherapy, and sometimes minor surgery (e.g., Achilles tendon lengthening), most are able to walk until age 12 yr. Ambulation is important not only for postponing the psychologic depression that accompanies the loss of an aspect of personal independence but also because scoliosis usually does not become a major complication as long as a patient remains ambulatory, even for as little as 1?hr/day; scoliosis often becomes rapidly progressive after confinement to a wheelchair.

The relentless progression of *weakness* continues into the 2nd decade. The function of distal muscles is usually relatively well enough preserved, allowing the child to continue to use eating utensils, a pencil, and a computer keyboard. Respiratory muscle involvement is expressed as a weak and ineffective cough, frequent pulmonary infections, and decreasing respiratory reserve. Pharyngeal weakness may lead to episodes of aspiration, nasal regurgitation of liquids, and an airy or nasal voice quality. The function of the extraocular muscles remains well preserved. Incontinence due to anal and urethral sphincter weakness is an uncommon and very late event.

Contractures most often involve the ankles, knees, hips, and elbows. Scoliosis is common. The thoracic deformity further compromises pulmonary capacity and compresses the heart. Scoliosis may be uncomfortable or painful. Enlargement of the calves (pseudohypertrophy) and wasting of thigh muscles is a classic feature. The enlargement is caused by hypertrophy of some muscle fibers, infiltration of muscle by fat, and proliferation of collagen. After the calves, the next most common site of muscular hypertrophy is the tongue, followed by muscles of the forearm. Fasciculations of the tongue do not occur.

Unless ankle contractures are severe, ankle jerks remain well preserved until terminal stages. The knee jerks may be present until about 6 yr of age but are less brisk than the ankle jerks and are eventually lost. In the upper extremities, the brachioradialis reflex is usually stronger than the biceps or triceps brachii reflexes.

Cardiomyopathy is a constant feature of this disease. The severity of cardiac involvement does not necessarily correlate with the degree of skeletal muscle weakness. Some patients die early of severe cardiomyopathy while still ambulatory; others in terminal stages of the disease have well-compensated cardiac function.

Intellectual impairment occurs in all patients, although only 20–30% have an IQ less than 70. The majority have learning disabilities that still allow them to function in a regular classroom,

---

particularly if remedial help is available. A few patients are profoundly mentally retarded, but there is no correlation with the severity of the myopathy. Epilepsy is slightly more common than in the general pediatric population.

The degenerative changes and fibrosis of muscle constitute a painless process. Myalgias and muscle spasms do not occur. Calcinosis of muscle is rare.

Death occurs usually at about 18 yr of age. The causes of death are respiratory failure in sleep, intractable heart failure, pneumonia, or occasionally aspiration and airway obstruction.

In *Becker muscular dystrophy*, boys remain ambulatory until late adolescence or early adult life. Calf pseudohypertrophy, cardiomyopathy, and elevated serum levels of creatine phosphokinase (CK) are similar to those of patients with Duchenne dystrophy. Learning disabilities are less frequent. The onset of weakness is later in Becker than in Duchenne dystrophy. Death often occurs in the mid to late 20s; fewer than half of patients are still alive by age 40 yr; these survivors are severely disabled.

Laboratory Findings.

The serum CK level is consistently greatly elevated in Duchenne muscular dystrophy, even in presymptomatic stages, including at birth. The usual serum concentration is 15,000–35,000?IU/L (normal <160?IU/L). A normal serum CK level is incompatible with the diagnosis of Duchenne dystrophy, although in terminal stages of the disease the serum CK value may be considerably lower than it was a few years earlier because there is less muscle to degenerate. Other lysosomal enzymes present in muscle, such as aldolase and aspartate aminotransferase, are also increased but are less specific.

Cardiac assessment by echocardiography, electrocardiogram (ECG), and chest roentgenogram is essential and should be repeated periodically. After the diagnosis is established, patients should be referred to a pediatric cardiologist for long-term cardiac care.

Electromyography (EMG) shows characteristic myopathic features but is not specific for Duchenne muscular dystrophy. No evidence of denervation is found. Motor and sensory nerve conduction velocities are normal.

Diagnosis.

A specific *molecular genetic diagnosis* is possible by demonstrating deficient or

defective dystrophin by immunohistochemical staining of sections of muscle biopsy tissue or by DNA analysis from peripheral blood. Confirmation of the diagnosis by one of these methods should be done in every case. If the blood PCR is diagnostic, muscle biopsy may be deferred, but if it is normal and clinical suspicion is high, the more specific dystrophin immunocytochemistry test performed on muscle biopsy sections detects the one third of cases that do not show a PCR abnormality. Dystroglycans and other sarcolemmal regional proteins, such as merosin and sarcoglycans, also can be tested, because they may be secondarily decreased.

The *muscle biopsy* is diagnostic and shows characteristic changes (Figs. 600–1 and 600–2). Myopathic changes include endomysial connective tissue proliferation, scattered degenerating and regenerating myofibers, foci of mononuclear inflammatory cell infiltrates as a reaction to muscle fiber necrosis, mild architectural changes in still functional muscle fibers, and many dense fibers. These hypercontracted fibers probably result from segmental necrosis at another level, allowing calcium to enter the site of breakdown of the sarcolemmal membrane and trigger a contraction of the whole length of the muscle fiber. Calcifications within myofibers are correlated with secondary ß-dystroglycan deficiency.

The decision about whether muscle biopsy should be performed to establish the diagnosis sometimes presents problems. If there is a family history of the disease, particularly in the case of an involved brother whose diagnosis has been confirmed, a patient with typical clinical features of Duchenne muscular dystrophy and high concentrations of serum CK probably does not need to undergo biopsy. The result of the polymerase chain

Figure 600.1-1 Muscle biopsy of a 4-yr-old boy with Duchenne muscular dystrophy. Both atrophic and hypertrophic muscle fibers are seen, and some fibers are degenerating (deg). Connective tissue (c) between muscle fibers is increased. (Hematoxylin & eosin, ×400.)

reaction (PCR) may also influence whether to perform a muscle biopsy. A first case in a family, even if the clinical features are typical, should have the diagnosis confirmed to ensure that another myopathy is not masquerading as Duchenne dystrophy. The most common muscles sampled are the vastus lateralis (quadriceps femoris) and the gastrocnemius.

Genetic Etiology and Pathogenesis.

Despite the X-linked recessive inheritance in Duchenne muscular dystrophy, about 30% of patients are new mutations, and the mother is not a carrier. The female carrier state usually shows no muscle weakness or any clinical expression of the disease, but affected girls are occasionally encountered, usually having much milder weakness than boys. These symptomatic girls are explained by the Lyon hypothesis in which the normal X chromosome becomes inactivated and the one with the gene deletion is active (see Chapter 69). The full clinical picture of Duchenne dystrophy has occurred in several girls with Turner syndrome in whom the single X chromosome must have had the Xp21 gene deletion.

The asymptomatic carrier state of Duchenne dystrophy is associated with elevated serum CK values in 80% of cases. The level of increase is usually in the magnitude of hundreds or a few thousand but does not have the extreme values noted in affected males. Prepubertal girls who are carriers of the dystrophy also have increased serum CK values, with highest levels at 8–12 yr of age. Approximately 20% of carriers have normal serum CK values. If the mother of an affected boy has normal CK levels, it is unlikely that her daughter can be identified as a carrier by measuring CK. Muscle biopsy of suspected female carriers may detect an additional 10% in whom serum CK is not elevated; a specific genetic diagnosis using PCR on peripheral blood is definitive.

Detection of the carrier state by serum CK or muscle biopsy will become obsolete because of discoveries in the molecular genetics of Duchenne muscular dystrophy. The Xp2l site of the Duchenne gene has more than 2,000?kb, but Duchenne DNA encompasses only 14?kb; the entire gene sequence has been mapped.

A 427-kd cytoskeletal protein known as *dystrophin* is encoded by the gene at the Xp21.2 locus. This subsarcolemmal protein attaches to the sarcolemmal membrane overlying the A band and M band of the myofibrils and consists of four distinct regions or domains: the amino terminus contains 250 amino acids and is related to the *N*-actin binding site of a-actinin; the second domain is the largest, with 2,800 amino acids, and contains many repeats, giving it a characteristic rod shape; a third

Figure 600.1-2 Dystrophin is demonstrated by immunohistochemical reactivity in the muscle biopsies of a normal term male neonate*(A)*; a 10-yr-old boy with limb-girdle muscular dystrophy *(B)*; a 6-yr-old boy with Duchenne muscular dystrophy *(C)*; and a 10-yr-old boy with Becker muscular dystrophy *(D)*. In the normal condition and also in non–X-linked muscular dystrophies in which dystrophin is not affected, the sacrolemmal membrane of every fiber is strongly stained, including atrophic and hypertrophic fibers. In Duchenne dystrophy, most myofibers express no detectable dystrophin, but a few scattered fibers known as “revertant fibers” show near-normal immunoreactivity. In Becker muscular dystrophy, the abnormal dystrophin molecule is expressed as thin, pale-staining of the sarcolemma in which reactivity varies not only between myofibers but also along the circumference of individual fibers (×250).

cysteine-rich domain is related to the carboxyl terminus of a-actinin; and the final carboxyl-terminal domain of 400 amino acids is unique to dystrophin and to a dystrophin-related protein encoded by chromosome 6. Dystrophin is first detected in developing human fetal muscle at the 11th wk of gestation. Dystrophin mRNA normally is detected in cardiac and smooth muscle as well as in skeletal muscle and brain. All of these tissues show various degrees of clinical involvement.

The molecular defects in the dystrophinopathies are of various types: intragenic deletions, duplications, or point mutations of nucleotides. About 65% of patients have deletions, and only 7% exhibit duplications. The site or size of the intragenic abnormality does not always correlate well with the phenotypic severity; in both Duchenne and Becker forms the mutations are mainly near the middle of the gene, involving deletions of exons 46–51. Phenotypic or clinical variations are explained by the alteration of the translational reading frame of mRNA, which results in unstable, truncated dystrophin molecules and severe, classic Duchenne dystrophy; mutations that preserve the reading frame still permit translation of coding sequences further downstream on the gene and produce a semifunctional dystrophin, expressed clinically as Becker muscular dystrophy. An even milder form of adult onset, formerly

known as *quadriceps myopathy*, is also caused by an abnormal dystrophin molecule. The clinical spectrum of the dystrophinopathies not only includes the classic Duchenne and Becker forms but ranges from a severe neonatal muscular dystrophy to asymptomatic children with persistent elevation of serum CK levels greater than 1,000?IU/L.

The absence of dystrophin leads to a secondary reduction in several dystrophin-associated glycoproteins in the sarcolemma, which results in loss of linkage to the extracellular matrix and renders the sarcolemma even more susceptible to necrosis. Dystroglycan, often secondarily reduced in Duchenne muscular dystrophy, also is essential for normal brain development, for anchoring radial glia, and for intercellular adhesion in particular.

Analysis of the dystrophin protein requires a muscle biopsy and is demonstrated by Western blot analysis or in tissue sections by immunohistochemical methods using either fluorescence or light microscopy of antidystrophin antisera (see Fig. 600–2). In classic Duchenne dystrophy, levels of less than 3% of normal are found; in Becker muscular dystrophy, the molecular weight of dystrophin is reduced to 20–90% of normal in 80% of patients, but in 15% the dystrophin is of normal size but reduced in quantity, and 5% have an abnormally large protein caused by excessive duplications or repeats of codons. Selective immunoreactivity of different parts of the dystrophin molecule in sections of muscle biopsy material distinguishes the Duchenne and Becker forms (Fig. 600–3). The demonstration of deletions and duplications also can be made from blood samples by the more rapid PCR, which identifies as many as 98% of deletions by amplifying 18 exons but cannot detect duplications. The diagnosis can thus be confirmed at the molecular genetic level from either the muscle biopsy material or from peripheral blood, although as many as one third of boys with Duchenne or Becker dystrophy have a false-normal blood PCR; all cases of dystrophinopathy are detected by muscle biopsy.

Figure 600.1-3 Quadriceps femoris muscle biopsy specimens from a 4-yr-old boy with Becker muscular dystrophy. *A*, Myofibers vary greatly in size, with both atrophic and hypertrophic forms; at the right is a zone of degeneration and necrosis infiltrated by macrophages, similar to Duchenne muscular dystrophy. (Hematoxylin-eosin, ×250.) Immunoreactivity using antibodies against the dystrophin molecule in the rod domain *(B)*, carboxyl-terminus *(C)*, and amino terminus *(D)* all show deficient but not totally absent dystrophin expression; most fibers of all sizes retain some dystrophin in parts of the sarcolemma but not around the entire circumference in cross section. Alternatively, the prominence of dystrophin is less, appearing weak, when compared with the simultaneously incubated normal control from another child of similar age *(E)*. *F*, Merosin expression is normal in this patient with Becker dystrophy, in both large and small myofibers, and is lacking only in frankly necrotic fibers. Compare with classic Duchenne muscular dystrophy illustrated in Figure 600–2*C* and with Figure 600–5.

The same methods of DNA analysis from blood samples may be applied for carrier detection in female relatives at risk, such as sisters and cousins, and to determine whether the mother is a carrier or whether a new mutation occurred in the embryo. Prenatal diagnosis is possible as early as the 12th wk of gestation by sampling chorionic villi for DNA analysis by Southern blot or PCR and is confirmed in aborted fetuses with Duchenne dystrophy by immunohistochemistry for dystrophin in muscle.

Treatment.

There is neither a medical cure for this disease nor a method of slowing its progression. Much can be done to treat complications and to improve the quality of life of affected children. *Cardiac decompensation* often responds well to digoxin, at least in early stages. *Pulmonary infections* should be promptly treated. Patients should avoid contact with children who have obvious respiratory or other contagious illnesses. Immunizations for influenza virus and routine vaccinations are indicated.

Preservation of a good *nutritional state* is important. Duchenne muscular dystrophy is not a vitamin deficiency disease, and excessive doses of vitamins should be avoided. Adequate calcium intake is important to minimize osteoporosis in boys confined to a wheelchair, and fluoride supplements may also be given, particularly if the local drinking water is not fluoridated. Because sedentary children burn fewer calories than active children and because of depression as an additional factor, these children tend to eat excessively and gain weight. Obesity makes a patient with myopathy even less functional because part of the limited reserve muscle strength is dissipated in lifting the weight of excess subcutaneous adipose tissue. Dietary restrictions with supervision may be needed.

Physiotherapy delays but does not always prevent contractures. At times, contractures may actually be useful in functional rehabilitation. For example, if contractures prevent extension of the elbow beyond 90 degrees and the muscles of the upper limb no longer are strong enough to overcome gravity, the elbow contractures are functionally beneficial in fixing an otherwise flail arm and in allowing the patient to eat and write. Surgical correction of the elbow contracture may be technically feasible, but the result may be deleterious. Physiotherapy contributes little to muscle strengthening because patients usually are already using their entire reserve for daily function, and exercise cannot further strengthen involved muscles. Excessive exercise may actually accelerate the process of muscle fiber degeneration.

The discovery of the dystrophin molecule, its encoding gene, and the specific mutations in Duchenne and Becker muscular dystrophies raises the theoretical potential of a cure by molecular genetic engineering. One experimental approach is *myoblast transfer therapy*, in which normal myoblasts from the muscle of a genetically close relative, usually the father, are cultured in vitro and then injected into dystrophic muscles with the expectation that they will form healthy myofibers with normal dystrophin to replace degenerating fibers. A major drawback is the requirement for immunosuppression to prevent rejection of the foreign cells. The results in cases without rejection phenomena have not been encouraging. Another potential but unproven approach is the introduction by intramuscular injection or a viral vector of a recombinant dystrophin gene.

Other treatment of human patients with Duchenne dystrophy involves the use of prednisone, prednisolone, deflazacort, or other steroids. Glucocorticoids decrease

the rate of apoptosis or programmed cell death of myotubes during ontogenesis and theoretically may decelerate the myofiber necrosis in muscular dystrophy. Strength usually improves initially, but the long-term complications of chronic steroid therapy, including considerable weight gain and osteoporosis, may offset this advantage or even result in greater weakness than might have occurred in the natural course of the disease. Also, fluorinated steroids, such as dexamethasone, induce myopathy by altering the myotube abundance of ceramide.

600.2 Emery-Dreifuss Muscular Dystrophy

Emery-Dreifuss muscular dystrophy, also known as *scapuloperoneal* or *scapulohumeral muscular dystrophy*, is a rare X-linked recessive dystrophy. The locus is on the long arm within the large Xq28 region that includes other mutations that cause myotubular myopathy, neonatal adrenoleukodystrophy, and the Bloch-Sulzberger type of incontinentia pigmenti; it is far from the gene for Duchenne muscular dystrophy on the short arm of the X chromosome. Another, rarer, form of Emery-Dreifuss dystrophy is transmitted as an autosomal dominant trait and is localized at 1q. This form may present quite late, in adolescence or early adult life, although the muscular and cardiac symptoms and signs are similar, and sudden death from ventricular fibrillation is a risk.

Clinical manifestations begin in middle childhood, but many patients survive to late adult life because of the slow progression of its course. Hypertrophy of muscles does not occur. Contractures of elbows and ankles develop early, and muscle becomes wasted in a scapulohumeroperoneal distribution. Facial weakness does not occur; this disease is thus distinguished clinically from autosomal dominant scapulohumeral and scapuloperoneal syndromes of neurogenic origin. Myotonia is absent. Intellectual function is normal. Cardiomyopathy is severe and is often the cause of death, more frequently from conduction defects and sudden ventricular fibrillation than from intractable myocardial failure. The serum CK value is only mildly elevated, further distinguishing this disease from other X-linked recessive muscular dystrophies.

Nonspecific myofiber necrosis and endomysial fibrosis are seen in the muscle biopsy. Many centronuclear fibers and selective histochemical type I muscle fiber atrophy may cause confusion with myotonic dystrophy. The defective gene in the X-linked form is called emerin and, unlike other dystrophies in which the defective gene is expressed at the sarcolemmal membrane, emerin is expressed at the nuclear membrane; the emerin protein may be demonstrated immunocytochemically in the muscle biopsy for definitive diagnosis. Emerin also may be tested as a genetic marker in blood. The defective protein in the autosomal dominant form is called lamin-A-C and also is a nuclear membrane protein with several subtypes and different mutations demonstrated. Treatment should be supportive, with special attention to cardiac conduction defects, and may require medications or a pacemaker.

600.3 Myotonic Muscular Dystrophy

Myotonic dystrophy (Steinert disease) is the second most common muscular dystrophy in North America, Europe, and Australia, having an incidence of 1:30,000 general population. It is inherited as an autosomal dominant trait.

Myotonic dystrophy is an example of a genetic defect causing dysfunction in multiple organ systems. Not only is striated muscle severely affected, but smooth muscle of the alimentary tract and uterus is also involved; cardiac function is altered; and patients have multiple and variable endocrinopathies, immunologic deficiencies, cataracts, dysmorphic facies, intellectual impairment, and other neurologic abnormalities.

Clinical Manifestations.

In the usual clinical course, excluding the severe neonatal form, infants may appear almost normal at birth, or facial wasting and hypotonia may already be early expressions of the disease. The facial appearance is characteristic, consisting of an inverted V-shaped upper lip, thin cheeks, and scalloped, concave temporalis muscles (Fig. 600–4). The head may be narrow, and the palate is high and arched because the weak temporal and pterygoid muscles in late fetal life do not exert sufficient lateral forces on the developing head and face.

Weakness is mild in the first few years. Progressive wasting of distal muscles becomes increasingly evident, particularly involving intrinsic muscles of the hands. The thenar and hypothenar eminences are flattened, and the atrophic dorsal interossei leave deep grooves between the fingers. The dorsal forearm muscles

Figure 600.3-4 Facial weakness, inverted V-shaped upper lip, and loss of muscle mass in the temporal fossae are characteristic of myotonic muscular dystrophy, even in infancy, as seen in this 8-mo-old girl.

and anterior compartment muscles of the lower legs also become wasted. The tongue is thin and atrophic. Wasting of the sternocleidomastoids gives the neck a long, thin, cylindric contour. Proximal muscles also eventually undergo atrophy, and scapular winging appears. Difficulty with climbing stairs and Gowers sign are progressive. Tendon stretch reflexes are usually preserved.

The distal distribution of muscle wasting in myotonic dystrophy is an exception to the general rule of myopathies having proximal and neuropathies having distal distribution patterns. The muscular atrophy and weakness in myotonic dystrophy are slowly progressive throughout childhood and adolescence and continue into adulthood. It is rare for patients with myotonic dystrophy to lose the ability to walk even in late adult life, although splints or bracing may be required to stabilize the ankles.

Myotonia, a characteristic feature shared by few other myopathies, does not occur in infancy and is usually not clinically or even electromyographically evident until about age 5 yr. Exceptional patients develop it as early as age 3 yr. Myotonia is a very slow relaxation of muscle after contraction, regardless of whether that contraction was voluntary or was induced by a stretch reflex or electrical stimulation. During physical examination, myotonia may be demonstrated by asking the patient to make tight fists and then to quickly open the hands. It may be induced by striking the thenar eminence with a rubber percussion hammer, and it may be detected by watching the involuntary drawing of the thumb across the palm. Myotonia may also be demonstrated in the tongue by pressing the edge of a wooden tongue blade against its dorsal surface and by observing a deep furrow that disappears slowly. The severity of myotonia does not necessarily parallel the degree of weakness, and the weakest muscles often have only minimal myotonia. Myotonia is not a painful muscle spasm. Myalgias do not occur in myotonic dystrophy.

The *speech* of patients with myotonic dystrophy is often articulated poorly and is slurred because of the involvement of the muscles of the face, tongue, and pharynx. Difficulties with swallowing sometimes occur. Aspiration pneumonia is a risk in severely involved children. Incomplete external ophthalmoplegia may sometimes result from extraocular muscle weakness.

Smooth muscle involvement of the *gastrointestinal tract* results in slow gastric emptying, poor peristalsis, and constipation. Some patients have encopresis associated with anal sphincter weakness. Women with myotonic dystrophy may have ineffective or abnormal uterine contractions during labor and delivery.

Cardiac involvement is usually manifested as heart block in the Purkinje conduction system and arrhythmias rather than as cardiomyopathy, unlike most other muscular dystrophies.

Endocrine abnormalities involve many glands and appear at any time during the course of the disease so that re-evaluation of endocrine status must be done annually. Hypothyroidism is common; hyperthyroidism may occur rarely. Adrenocortical insufficiency may lead to an addisonian crisis even in infancy. Diabetes mellitus is common in patients with myotonic dystrophy; some children have a disorder of insulin release rather than defective insulin production. Onset of puberty may be precocious or, more often, delayed. Testicular atrophy and testosterone deficiency are common in adults and are responsible for a high incidence of male infertility. Ovarian atrophy is rare. Frontal baldness is also characteristic in males and often begins in adolescence.

Immunologic deficiencies are common in myotonic dystrophy. The plasma IgG level is often low.

Cataracts occur frequently in myotonic dystrophy. They may be congenital, or they may begin at any time during childhood or adult life. Early cataracts are detected only by slit lamp examination; periodic examination by an ophthalmologist is recommended. Visual evoked potentials are often abnormal in children with myotonic dystrophy and are unrelated to cataracts. They are not usually accompanied by visual impairment.

About half of the patients with myotonic dystrophy are intellectually impaired, but severe mental retardation is unusual. The remainder are of average or occasionally above average intelligence. Epilepsy is not common.

A severe neonatal form of myotonic dystrophy appears in a minority of involved infants born to mothers with myotonic dystrophy. Clubfoot deformities alone or more extensive congenital contractures of many joints may involve all extremities and even the cervical spine. Generalized hypotonia and weakness are present at birth. Facial wasting is prominent. Some infants require gavage feeding or even ventilator support for respiratory muscle weakness or apnea. One or both leaves of the diaphragm may be nonfunctional. The abdomen becomes distended with gas in the stomach and intestine because of poor peristalsis from smooth muscle weakness. The distention further compromises respiration. Inability to empty the rectum may compound the problem. About 75% of severely affected neonates die within the first year.

Laboratory Findings.

The classic myotonic EMG is not found in infancy but may appear in toddlers or during the early school years. The levels of serum CK and other serum enzymes from muscle may be normal or only mildly elevated in the hundreds (never the thousands).

An ECG should be performed annually in early childhood. Ultrasonic imaging of the abdomen may be indicated in affected infants to determine diaphragmatic function. Roentgenograms of the chest and abdomen and contrast studies of gastrointestinal motility may be needed.

Endocrine assessment should be undertaken to determine thyroid and adrenal cortical function and to verify carbohydrate metabolism (glucose tolerance test). Immunoglobulins should be examined, and, if needed, more extensive immunologic studies should be performed.

Diagnosis.

The primary diagnostic test is a DNA analysis of blood to demonstrate the abnormal expansion of the CTG repeat. Prenatal diagnosis also is feasible. The muscle biopsy in older children shows many muscle fibers with central nuclei and selective atrophy of histochemical type I fibers, but degenerating

fibers are usually few and widely scattered, and there is little or no fibrosis of muscle. Intrafusal fibers of muscle spindles are also abnormal. In young children with the common form of the disease, the biopsy specimen may even appear normal or may at least not show myofiber necroses, which is a striking contrast with Duchenne muscular dystrophy. In the severe neonatal form of myotonic dystrophy, the muscle biopsy reveals maturational arrest in various stages of development in some and congenital muscle fiber–type disproportion in others. It is likely that the sarcolemmal membrane of muscle fibers not only has abnormal properties of electrical polarization but is also incapable of responding to trophic influences of the motor neuron. Muscle biopsy is not usually required for diagnosis, which in typical cases can be based on the clinical manifestations.

Genetics.

The genetic defect in myotonic muscular dystrophy is on chromosome 19 at the 19q13 locus. It consists of an expansion of the *DM* gene that encodes a serine-threonine kinase *(DMPK)*, with numerous repeats of the cytosine-thymine-guanine (CTG) codon. Expansions range from 50 to over 2,000, with the normal alleles of this gene ranging in size from 5 to 37; the larger the expansion, the more severe the clinical expression, with the largest expansions seen in the severe neonatal form. Rarely, the disease is associated with no detectable repeats, perhaps a spontaneous correction of a previous expansion but a phenomenon still incompletely understood. A second type of myotonic dystrophy (PROMM) is a clinical entity linked to at least two different chromosomal loci than classic myotonic dystrophy but one that shares a common unique pathogenesis in being mediated by a mutant mRNA. Defects in RNA splicing explain the insulin resistance in myotonic dystrophies as well as the myotonia.

Both clinical and genetic expression may vary between siblings or between an affected parent and child. In the severe neonatal form of the disease, the mother is the transmitting parent in 94% of cases, a fact not explained by increased male infertility alone. Genetic analysis reveals that such infants usually have many more repeats of the CTG codon than do patients with the more classic form of the disease. Myotonic dystrophy often exhibits a pattern of *anticipation* in which each successive generation has a tendency to be more severely involved than the previous generation.

Treatment.

There is no specific medical treatment, but the cardiac, endocrine, gastrointestinal, and ocular complications can often be treated. Physiotherapy and orthopedic treatment of contractures in the neonatal form of the disease may be beneficial.

Myotonia may be diminished, and function may be restored by drugs that raise the depolarization threshold of muscle membranes, such as mexiletine, phenytoin, carbamazepine, procainamide, and quinidine sulfate. These drugs also have cardiotropic effects; thus, cardiac evaluation is important before prescribing them. Phenytoin and carbamazepine are used in doses similar to their use as anticonvulsants (see Chapter 586.4); serum concentrations of 40–80?µmol/L for phenytoin and 35–50?µmol/L for carbamazepine should be maintained. If a patient's disability is caused mainly by weakness rather than by myotonia, these drugs will be of no value.

OTHER MYOTONIC SYNDROMES

Most patients with myotonia have myotonic dystrophy. Myotonia is not specific for this disease and occurs in several rarer conditions.

Myotonic chondrodystrophy (Schwartz-Jampel disease) is a rare congenital disease characterized by generalized muscle hypertrophy and weakness. Dysmorphic phenotypical features and the roentgenographic appearance of long bones are reminiscent of Morquio disease (see Chapter 77), but abnormal mucopolysaccharides are not found. Dwarfism, joint abnormalities, and blepharophimosis are present. Several patients have been the products of consanguinity, suggesting autosomal recessive inheritance. The muscle protein perlecan, encoded by the *SJS1* gene, a large heparan sulfate proteoglycan of basement membranes and cartilage, is defective in some cases of Schwartz-Jampel disease and explains both the muscular hyperexcitability and the chondrodysplasia.

EMG reveals continuous electrical activity in muscle fibers closely resembling or identical to myotonia. Muscle biopsy reveals nonspecific myopathic features, which are minimal in some cases and pronounced in others. The sarcotubular system is dilated.

Myotonia congenita (Thomsen disease) is a channelopathy and is characterized by weakness and generalized muscular hypertrophy so that affected children resemble bodybuilders. Myotonia is prominent and may develop at age 2–3 yr, earlier than in myotonic dystrophy. The disease is clinically stable and is apparently not progressive for many years. Muscle biopsy specimens show minimal pathologic changes, and the EMG demonstrates myotonia. Various families are described as showing either autosomal dominant (Thomsen disease) or recessive (Becker disease, not to be confused with Becker/Duchenne muscular dystrophy) inheritance. Rarely, myotonic dystrophy and myotonia congenita coexist in the same family. Both the autosomal dominant and autosomal recessive forms of myotonia congenita have been mapped to the same 7q35 locus. This gene is important for the integrity of chloride channels of the sarcolemmal and T-tubular membranes.

Paramyotonia is a temperature-related myotonia that is aggravated by cold and alleviated by warm external temperatures. Patients have difficulty when swimming in cold water or if they are dressed inadequately in cold weather. Paramyotonia congenita is a defect in a gene at the 17q13.1-13.3 locus, the identical locus identified in hyperkalemic periodic paralysis. By contrast with myotonia congenita, paramyotonia is a disorder of the sodium channel. Myotonic dystrophy also is a sodium channelopathy.

In sodium channelopathies, exercise produces increasing myotonia, whereas in chloride channelopathies, exercise reduces the myotonia. This is easily tested during examination by asking patients to close the eyes forcefully and open them repeatedly; it becomes progressively more difficult in sodium channel disorders and

progressively easier in chloride channel disorders.

600.4 Limb-Girdle Muscular Dystrophy

This term encompasses a group of progressive hereditary myopathies that mainly affect muscles of the hip and shoulder girdles. Distal muscles also eventually become atrophic and weak. Hypertrophy of the calves and ankle contractures develop in some forms, causing potential confusion with Becker muscular dystrophy.

The initial *clinical manifestations* rarely appear before middle or late childhood or may be delayed until early adult life. Low back pain may be a presenting complaint because of the lordotic posture resulting from gluteal muscle weakness. Confinement to a wheelchair usually becomes obligatory at about 30 yr of age. The rate of progression varies from one pedigree to another but is uniform within a kindred. Although weakness of neck flexors and extensors is universal, facial, lingual, and other bulbar-innervated muscles are rarely involved. As weakness and muscle wasting progress, tendon stretch reflexes become diminished. Cardiac involvement is unusual. Intellectual function is generally normal. The clinical differential diagnosis of limb-girdle muscular dystrophy includes juvenile spinal muscular atrophy

(Kugelberg-Welander disease), myasthenia gravis, and metabolic myopathies.

Most cases of limb-girdle muscular dystrophy are of autosomal recessive inheritance, but some families express an autosomal dominant trait. The latter often follows a benign course with little functional impairment.

The EMG and muscle biopsy show confirmatory evidence of muscular dystrophy, but none of the findings is specific enough to make the definitive *diagnosis* without additional clinical criteria. In some cases, adhalen, a dystrophin-related glycoprotein of the sarcolemma, is deficient; this specific defect may be demonstrated in the muscle biopsy by immunocytochemistry. Increased serum CK level is usual, but the magnitude of elevation varies among families. The ECG is usually unaltered.

In one autosomal dominant form of limb-girdle muscular dystrophy, a *genetic defect* has been localized to the long arm of chromosome 5. In the autosomal recessive disease, it is on the long arm of chromosome 15. A mutated dystrophin-associated protein in the sarcoglycan complex (sarcoglycanopathy) is responsible for some cases of autosomal recessive limb-girdle muscular dystrophy. Adhalen is a-sarcoglycan; other limb-girdle dystrophies due to deficiencies in ß-, ?-, and d-sarcoglycan also occur. In normal smooth muscle, a- is replaced by e-sarcoglycan

and the others are the same.

Another group of limb-girdle dystrophies are caused by allelic mutations of the dysferlin *(DYSF)* gene, another gene expressing a protein essential to structural integrity of the sarcolemma, though not associated with the dystrophin-glycoprotein complex. *DYSF* interacts with caveolin-3 or calpain-3, and *DYSF* deficiency may be secondary to defects in these other gene products. Autosomal recessive (Miyoshi myopathy) and autosomal dominant traits are documented. Both are slowly progressive myopathies with onset in adolescence or young adult life and may affect distal as well as proximal muscles. Cardiomyopathy is rare. Chronically elevated serum CK in the thousands is found in dysferlinopathies. Ultrastructure shows a thickened basal lamina over defects in the sarcolemma and replacement of the sarcolemma by multiple layers of small vesicles. Regenerating myofibers outnumber degenerating myofibers.

600.5 Facioscapulohumeral Muscular Dystrophy

Facioscapulohumeral muscular dystrophy, also known as **Landouzy-Dejerine disease**, is probably not a single disease entity but a group of diseases with similar clinical manifestations. Autosomal dominance is the rule; *genetic anticipation* is often found within several generations of a family, the succeeding more severely involved at an earlier age than the preceding. The genetic mechanism in autosomal dominant facioscapulohumeral dystrophy involves integral deletions of a 3.3-kb tandem repeat (D4Z4) in the subtelomeric region at the 4q35 locus. A closely homologous 3.3-kb repeat array at the subtelomeric locus 10q26, with chromosomal translocation or sequence conversion between these two regions, possibly predisposes to the DNA rearrangement causing facioscapulohumeral dystrophy.

Clinical Manifestations.

Facioscapulohumeral dystrophy shows the earliest and most severe weakness in facial and shoulder girdle muscles. The facial weakness differs from that of myotonic dystrophy; rather than an inverted V-shaped upper lip, the mouth in facioscapulohumeral dystrophy is rounded and appears puckered because the upper and lower lips protrude. Inability to close the eyes completely in sleep is a common expression of upper facial weakness; some patients have extraocular muscle weakness, although ophthalmoplegia is rarely complete. Facioscapulohumeral dystrophy has been associated with Möbius syndrome on rare occasions. Pharyngeal and tongue weakness may be absent and is never as severe as the facial involvement. Hearing loss, which may be subclinical, and retinal vasculopathy (indistinguishable from Coat syndrome) are associated features, particularly in *severe* cases of facioscapulohumeral dystrophy with early childhood onset.

Scapular winging is prominent, often even in infants. Flattening or even concavity of the deltoid contour is seen, and the biceps and triceps brachii muscles are wasted and weak. Muscles of the hip girdles and thighs also eventually lose strength and undergo atrophy, and Gowers sign and a Trendelenburg gait appear. Contractures are rare. Finger and wrist weakness occasionally is the first symptom. Weakness of the anterior tibial and peroneal muscles may lead to footdrop; this complication usually occurs only in advanced cases with severe weakness. Lumbar lordosis and kyphoscoliosis are common complications of axial muscle involvement. Calf hypertrophy is not a feature.

Facioscapulohumeral muscular dystrophy may also be a mild disease causing minimal disability. Clinical manifestations may not be expressed in childhood and are delayed into middle adult life. Unlike most other muscular dystrophies, asymmetry of

weakness is common.

Laboratory Findings.

Serum levels of CK and other enzymes vary greatly, ranging from normal or near normal to elevations of several thousand. ECG should be performed, although the anticipated findings are usually normal. EMG reveals nonspecific myopathic muscle potentials. Diagnostic molecular testing in both individual cases and within families is indicated for prediction.

Diagnosis and Differential Diagnosis.

Muscle biopsy distinguishes more than one form of facioscapulohumeral dystrophy, consistent with clinical evidence that several distinct diseases are embraced by the term *FSH dystrophy*. Muscle biopsy and EMG also distinguish the primary myopathy from a neurogenic disease with a similar distribution of muscular involvement. The general histopathologic findings in the muscle biopsy material are extensive proliferation of connective tissue between muscle fibers, extreme variation in fiber size with many hypertrophic as well as atrophic myofibers, and scattered degenerating and regenerating fibers. An "inflammatory" type of facioscapulohumeral muscular dystrophy is also distinguished, characterized by extensive lymphocytic infiltrates within muscle fascicles. Despite the resemblance of this form to inflammatory myopathies, such as polymyositis, there is no evidence of autoimmune disease, and steroids and immunosuppressive drugs do not alter the clinical course. A precise histopathologic diagnosis has important therapeutic implications. Mononuclear cell "inflammation" in a muscle biopsy sample of infants younger than 2 yr is usually facioscapulohumeral dystrophy.

Treatment.

Physiotherapy is of no value in regaining strength or in retarding progressive weakness or muscle wasting. Footdrop and scoliosis may be treated by orthopedic measures. Cosmetic improvement of the facial muscles of expression may be achieved by reconstructive surgery, which grafts a fascia lata to the zygomatic muscle and to the zygomatic head of the quadratus labiae superioris muscle.

600.6 Congenital Muscular Dystrophy

The term *congenital muscular dystrophy* is misleading because all muscular dystrophies are genetically determined. It is used to encompass several distinct diseases with a common characteristic of severe involvement at birth but that ironically usually follow a benign clinical course. Autosomal recessive inheritance is the rule.

Clinical Manifestations.

Infants often have contractures or arthrogryposis at birth and are diffusely hypotonic. The muscle mass is thin in the trunk and extremities. Head control is poor. Facial muscles may be mildly involved, but ophthalmoplegia, pharyngeal weakness, and weak sucking are not common. A minority have severe dysphagia and require gavage or gastrostomy. Tendon stretch reflexes may be hypoactive or absent. Arthrogryposis is common in all forms of congenital muscular dystrophy (see Chapter 599.9).

One form of congenital muscular dystrophy, the Fukuyama type, is the 2nd most common muscular dystrophy in Japan (after Duchenne dystrophy); it has also been reported in children of Dutch, German, Scandinavian, and Turkish ethnic backgrounds. In the Fukuyama variety, severe cardiomyopathy and malformations of the brain usually accompany the skeletal muscle involvement. Signs and symptoms related to these organs are prominent: cardiomegaly and heart failure, mental retardation, seizures, microcephaly, and failure to thrive. The genetic defect in Fukuyama congenital muscular dystrophy has been identified at the 8q31-33 locus in Japanese patients.

Neurologic disease may accompany forms of congenital muscular dystrophy other than Fukuyama disease. Mental and neurologic status are the most variable features; an apparently normal brain and normal intelligence do not preclude the diagnosis if other manifestations indicate this myopathy. The cerebral malformations that occur are not consistently of one type and vary from severe dysplasias (holoprosencephaly, lissencephaly) to milder conditions (agenesis of the corpus callosum, focal heterotopia of the cerebral cortex and subcortical white matter, cerebellar hypoplasia). Congenital muscular dystrophy is a consistent association with cerebral dysgenesis in the *Walker-Warburg syndrome* and in *muscle-eye-brain disease of Santavuori*. The neuropathologic findings are those of neuroblast migratory abnormalities in the cerebral cortex, cerebellum, and brain stem. Another

separate form of congenital muscular dystrophy is characterized by microcephaly and mental retardation.

Laboratory Findings.

Serum CK level is usually moderately elevated from several hundred to many thousand IU/L; only marginal increases are sometimes found. EMG shows nonspecific myopathic features. Investigation of all forms of congenital muscular dystrophy should include cardiac assessment and an imaging study of the brain. Muscle biopsy is essential for the diagnosis.

Diagnosis.

Muscle biopsy is diagnostic in the neonatal period or thereafter. An extensive proliferation of endomysial collagen envelops individual muscle fibers even at birth, also causing them to be rounded in cross-sectional contour by acting as a rigid sleeve, especially during contraction. The perimysial connective

Figure 600.6-5 Quadriceps femoris muscle biopsy of a 6-mo-old girl with congenital muscular dystrophy associated with merosin (a_2 -laminin) deficiency. *A*, Histologically, the muscle is infiltrated by a great proliferation of collagenous connective tissue; myofibers vary in diameter, but necrotic fibers are rare. *B*, Immunocytochemical reactivity for merosin (a_2 -laminin) is absent in all fibers, including the intrafusal myofibers of a muscle spindle seen at bottom. *C*, Dystrophin expression (rod domain) is normal. Compare with Figures 600–2 , 600–3 , and 600–6 .

Figure 600.6-6 Quadriceps femoris muscle biopsy of a 2-yr-old girl with congenital muscular dystrophy. *A*, The fascicular architecture of the muscle is severely disrupted, and muscle is replaced by fat and connective tissue; remaining small groups of myofibers of variable size are seen, including a muscle spindle at top. *B*, Merosin expression is normal in both extrafusal fibers of all sizes and in intrafusal spindle fibers. The severity of the myopathy does not relate to the presence or absence of merosin in congenital muscular dystrophy. Compare with Figure 600–5 .

tissue and fat are also increased, and the fascicular organization of the muscle may be disrupted by the fibrosis. Tissue cultures of intramuscular fibroblasts exhibit increased collagen synthesis, but the structure of the collagen is normal. Muscle fibers vary in diameter, and many show central nuclei, myofibrillar splitting, and other cytoarchitectural alterations. Scattered degenerating and regenerating fibers are seen. No inflammation or abnormal inclusions are found.

Immunocytochemical reactivity for merosin (a_2 chain of laminin) at the sarcolemmal region is absent in about half the cases and normally expressed in the others (Figs. 600–5 and 600–6). Merosin is a protein that binds the sarcolemmal membrane of the myofiber to the basal lamina or basement membrane. Its defect is a mutation of the *LAMA2* gene at the 6q22-q23 locus. The presence or absence of merosin does not always correlate with the severity of the myopathy or predict its course, but cases with merosin deficiency tend to have more severe cerebral involvement and myopathy. Adhalen (a-dystroglycan) may be secondarily reduced in some cases.

Treatment.

Only supportive therapy is available.

Chapter 601 - Endocrine Myopathies

Thyroid Myopathies.

(See also Part XXV , Section 2 .) Thyrotoxicosis causes proximal weakness and wasting accompanied by myopathic electromyographic changes. Thyroxine binds to myofibrils and, if in excess, impairs contractile function. Hyperthyroidism may also induce myasthenia gravis and hypokalemic periodic paralysis.

Hypothyroidism, whether congenital or acquired, consistently produces hypotonia and a proximal distribution of weakness. Although muscle wasting is most characteristic, one form of cretinism, the Kocher-Debré-Sémélaigne syndrome, is characterized by generalized pseudohypertrophy of weak muscles. Infants may have a herculean appearance reminiscent of myotonia congenita. The serum creatine phosphokinase (CK) level is elevated in hypothyroid myopathy and returns to normal after thyroid replacement therapy. Muscle biopsy material reveals myopathic changes, including myofiber necrosis and sometimes central cores.

Both the clinical and pathologic features of hyperthyroid myopathy and hypothyroid myopathy resolve after appropriate treatment of the thyroid disorder.

Hyperparathyroidism (see Chapter 567).

Most patients with primary hyperparathyroidism develop weakness, fatigability, and muscle wasting that are reversible after removal of the parathyroid adenoma.

Steroid-Induced Myopathy.

Both natural Cushing disease and iatrogenic Cushing syndrome due to exogenous corticosteroid administration may cause progressive proximal weakness, increased serum CK levels, and a myopathic electromyogram and muscle biopsy specimen (see Chapter 571). Myosin filaments may be selectively lost. Fluorinated steroids, such as dexamethasone, are the most likely to produce *steroid myopathy*. Dexamethasone alters the abundance of ceramides in myotubes in developing muscle. In patients with dermatomyositis or other myopathies treated with steroids, it is sometimes difficult to distinguish refractoriness of the disease from steroid-induced weakness, especially after long-term steroid administration. All patients who have been taking steroids for long periods develop a reversible type II myofiber atrophy;

this is a *steroid effect* but is not steroid myopathy unless it progresses to become a necrotizing myopathy.

Hyperaldosteronism (Conn syndrome) is accompanied by episodic and reversible weakness similar to that of periodic paralysis. The proximal myopathy may become irreversible in chronic cases. Elevated CK levels and even myoglobinuria sometimes occur during acute attacks.

Chapter 602 - Metabolic Myopathies

602.1 Periodic Paralyses (Potassium-Related)

Episodic, reversible weakness or paralysis known as *periodic paralysis* is associated with transient alterations in serum potassium levels, usually hypokalemia but occasionally hyperkalemia. All familial forms of periodic paralysis are caused by mutations in genes encoding voltage-gated ion channels in muscle: sodium, calcium, and potassium. During attacks, myofibers are electrically inexcitable, although the contractile apparatus can respond normally to calcium. The disorder is inherited as an autosomal dominant trait. It is precipitated in some patients by a heavy carbohydrate meal, insulin, adrenaline including that induced by emotional stress, hyperaldosteronism or hyperthyroidism, administration of amphotericin B, or ingestion of licorice. The defective genes are at the 17q13.1-13.3 locus in *hyperkalemic periodic paralysis*, the same as in paramyotonia congenita, and at the 1q31-32 locus in *hypokalemic periodic paralysis*.

In childhood, periodic paralysis is often an episodic event; patients are unable to move after awakening and gradually recover muscle strength during the next few minutes or hours. Muscles that remain active in sleep, such as the diaphragm and cardiac muscle, are not affected. Patients are normal between attacks, but in adult life the attacks become more frequent, and the disorder causes progressive myopathy with permanent weakness even between attacks.

Alterations in serum potassium level occur only during acute episodes and are accompanied by T-wave changes in the electrocardiogram (ECG). Hypokalemia may be due to alterations in calcium gradients. The creatine kinase (CK) level may be mildly elevated at those times. Muscle biopsy findings are often normal between attacks, but during an attack a vacuolar myopathy is demonstrated. Pathologic changes in the periodic paralyses are similar whether the disease is due to a sodium or potassium channel defect, suggesting that they may result from the recurrent paralytic state rather than the specific channelopathy. The vacuoles are dilated sarcoplasmic reticulum and invaginations of the extracellular space into the cytoplasm, and they may be filled with glycogen. Hypoglycemia does not occur.

602.2 Malignant Hyperthermia

(See also Chapters 65 and 599.4 .)

This syndrome is usually inherited as an autosomal dominant trait. It occurs in all patients with central core disease but is not limited to that particular myopathy. The gene is at the 19q13.1 locus in both central core disease and malignant hyperthermia without this specific myopathy. At least 15 separate mutations in this gene are associated with malignant hyperthermia. The gene programs the ryanodine receptor, a tetrameric calcium release channel in the sarcoplasmic reticulum, apposed to the voltage-gated calcium channel of the transverse tubule. It occurs rarely in Duchenne and other muscular dystrophies, in various other myopathies, and in an isolated syndrome not associated with other muscle disease. Affected children sometimes have peculiar facies. All ages are affected, including premature infants whose mothers underwent general anesthesia for cesarean section.

Acute episodes are precipitated by exposure to general anesthetics and occasionally to local anesthetic drugs. Patients suddenly develop extreme fever, rigidity of muscles, and metabolic and respiratory acidosis; the serum CK level rises to as high as 35,000?IU/L. Myoglobinuria may result in tubular necrosis and acute renal failure.

The muscle biopsy during an episode of malignant hyperthermia or shortly afterward shows widely scattered necrosis of muscle fibers known as rhabdomyolysis. Between attacks, the muscle biopsy is normal unless there is an underlying chronic myopathy.

It is important to recognize patients at risk for malignant hyperthermia because the attacks may be prevented by administering dantrolene sodium before an anesthetic is given. Identification of patients at risk, such as siblings of those who have experienced an episode, is done by the caffeine contracture test: A portion of fresh muscle biopsy tissue in a saline bath is attached to a strain gauge and exposed to caffeine and other drugs; an abnormal spasm is diagnostic. The syndrome receptor also may be demonstrated by immunochemistry in frozen sections of the muscle biopsy. The gene defect of the ryanodine receptor is present in 50% of patients; gene testing is available only for this genetic group. Another candidate gene is at the 1q31 locus.

Apart from the genetic disorder of malignant hyperthermia, some drugs may induce acute rhabdomyolysis with myoglobinuria and potential renal failure, but this usually occurs in patients who are predisposed by some other metabolic disease. Valproic acid, for example, may induce this process in children with mitochondrial cytopathies

or with carnitine palmitoyltransferase deficiency.

602.3 Glycogenoses

(See also Chapter 76 .)

Glycogenosis I (von Gierke disease) is not a true myopathy because the deficient liver enzyme, glucose-6-phosphatase, is not normally present in muscle. Nevertheless, children with this disease are hypotonic and mildly weak for unknown reasons.

Glycogenosis II (Pompe disease) is an autosomal recessively inherited deficiency of the glycolytic lysosomal enzyme acid maltase. Of the 12 known glycogenoses, type II is the only one with a defective lysosomal enzyme. The defective gene is at locus 17q23. Two forms are described. The infantile form is a severe generalized myopathy and cardiomyopathy. Patients have cardiomegaly and hepatomegaly and are diffusely hypotonic and weak. The serum CK level is greatly elevated. Muscle biopsy reveals a vacuolar myopathy with abnormal lysosomal enzymatic activities such as acid and alkaline phosphatases. Death in infancy or early childhood is usual.

The late childhood or adult form is a much milder myopathy without cardiac or hepatic enlargement. It may not become clinically expressed until later childhood or early adult life but may be symptomatic as myopathic weakness and hypotonia even in early infancy. The serum CK level is greatly elevated, and the muscle biopsy findings are diagnostic even in the presymptomatic stage.

The diagnosis of glycogenosis II is confirmed by quantitative assay of acid maltase activity in muscle or liver biopsy specimens. A rare KM variant of the milder form of acid maltase deficiency may show muscle acid maltase activity in the low normal range with only intermittent decreases to subnormal values, but the muscle biopsy findings are similar although milder. In another form, *Danon disease,* transmitted as an X-linked recessive trait at the Xq24 locus, the primary deficiency is *lysosomal membrane protein-2 (LAMP2)* and results in hypertrophic cardiomyopathy, proximal myopathy, and mental retardation.

Glycogenosis III (Cori-Forbes disease), deficiency of debrancher enzyme (amylo-1,6-glucosidase), is the most common of the glycogenoses but also the least severe. Hypotonia, weakness, hepatomegaly, and fasting hypoglycemia in infancy are common, but these features often resolve spontaneously, and patients become asymptomatic in childhood and adult life. Others experience slowly progressive distal muscle wasting, hepatic cirrhosis, and heart failure. Minor myopathic findings

including vacuolation of muscle fibers are found in the muscle biopsy specimen.

Glycogenosis IV (Andersen disease) is a deficiency of brancher enzyme, resulting in the formation of an abnormal glycogen molecule, amylopectin, in the liver, reticuloendothelial cells, and skeletal and cardiac muscle. Hypotonia, generalized weakness, muscle wasting, and contractures are the usual signs of myopathic involvement. Most patients die before age 4 yr because of hepatic or cardiac failure. A few children without neuromuscular manifestations have been described.

Glycogenosis V (McArdle disease) is due to muscle phosphorylase deficiency inherited as an autosomal recessive trait at locus 11q13. Exercise intolerance is the cardinal clinical feature. Physical exertion results in cramps, weakness, and myoglobinuria, but strength is normal between attacks. The serum CK level is elevated only during exercise. A characteristic clinical feature is lack of the normal rise in serum lactate level during ischemic exercise because of inability to convert pyruvate to lactate under anaerobic conditions in vivo. Myophosphorylase deficiency may be demonstrated histochemically and biochemically in the muscle biopsy tissue.

A rare *neonatal form of myophosphorylase deficiency* causes feeding difficulties in early infancy, may be severe enough to result in neonatal death, or may follow a course of slowly progressive weakness resembling a muscular dystrophy.

The long-term prognosis is good. Patients must learn to moderate their physical activities, but they do not develop severe chronic myopathic handicaps or cardiac involvement.

Glycogenosis VII (Tarui disease) is muscle phosphofructokinase deficiency. Although this disease is rarer than glycogenosis V, the symptoms of exercise intolerance, clinical course, and inability to convert pyruvate to lactate are identical. The distinction is made by biochemical study of the muscle biopsy specimen. It is transmitted as an autosomal recessive trait at the 1cenq32 locus.

602.4 Mitochondrial Myopathies

(See also Chapter 591.2 .)

Several diseases involving muscle, brain, and other organs are associated with structural and functional abnormalities of mitochondria, producing defects in aerobic cellular metabolism, the electron transport chain, and the Krebs cycle. The structural aberrations are best demonstrated by electron microscopy of the muscle biopsy sample, revealing abnormally shaped cristae and fusion of cristae to form paracrystalline structures. Histochemical study of the muscle biopsy reveals abnormal clumping of oxidative enzymatic activity, sometimes increased neutral lipids because of impaired lipid metabolism, and ragged-red muscle fibers with accumulations of membranous material beneath the muscle fiber membrane, best demonstrated by special stains. These characteristic histochemical and ultrastructural changes are most consistently seen only with point mutation in mitochondrial tRNA. The large mtDNA deletions of 5 or 7.4?kb (the single mitochondrial chromosome has 16.5?kb) are associated with defects in mitochondrial respiratory oxidative enzyme complexes, if as few as 2% of the mitochondria are affected, but minimal or no morphologic or histochemical changes may be noted in the muscle biopsy specimen, even by electron microscopy; hence, the quantitative biochemical studies of the muscle tissue are needed to confirm the diagnosis.

Several distinct mitochondrial diseases that primarily affect striated muscle or muscle and brain are identified. The *Kearns-Sayre syndrome* is characterized by the triad of progressive external ophthalmoplegia, pigmentary degeneration of the retina, and onset before age 20 yr. Heart block, cerebellar deficits, and high cerebrospinal fluid protein content are often associated. Visual evoked potentials are abnormal. Patients usually do not experience weakness of the trunk or extremities or dysphagia. Most cases are sporadic.

Chronic progressive external ophthalmoplegia may be isolated or accompanied by limb muscle weakness, dysphagia, and dysarthria. A few patients described as having *ophthalmoplegia plus* have additional central nervous system (CNS) involvement. Autosomal dominant inheritance is found in some pedigrees, but most cases are sporadic.

Myoclonic epilepsy and ragged-red fibers (MERRF) and the *MELAS syndrome*, an acronym for mitochondrial myopathy, encephalopathy, lactic acidosis, and strokelike episodes, are other mitochondrial disorders affecting children. The latter is characterized by stunted growth, episodic vomiting, seizures, and recurrent cerebral insults causing hemiparesis, hemianopia or even cortical blindness, and dementia. The disease behaves as a degenerative disorder, and children die within a few

years. Ragged-red fibers are characteristic of combined defects in oxidative respiratory complexes I and IV, although a few cases with complex V deficiency exhibit ragged-red fibers.

Other “degenerative” diseases of the CNS that also involve myopathy with mitochondrial abnormalities include *Leigh subacute necrotizing encephalopathy* (see Chapter 76.4) and *cerebrohepatorenal (Zellweger) disease* (see Chapter 75.2). Another recognized mitochondrial myopathy is *cytochrome-c-oxidase deficiency. Oculopharyngeal muscular dystrophy* is also fundamentally a mitochondrial myopathy. Many other rare diseases with only a few case reports are suspected of being mitochondrial disorders.

Mitochondrial DNA is distinct from the DNA of the cell nucleus and is inherited exclusively from the mother; mitochondria are present in the cytoplasm of the ovum but not in the head of the sperm, the only part that enters the ovum at fertilization. The rate of mutation of mitochondrial DNA is 10 times higher than that of nuclear DNA. The mitochondrial respiratory enzyme complexes each have subunits encoded either in mtDNA or in nuclear DNA. For example, complex II (succinate dehydrogenase, a Krebs cycle enzyme) has 4 subunits, all encoded in nuclear DNA; complex III (ubiquinol or cytochrome-b-oxidase) has 9 subunits, only one of which is

encoded by mtDNA and 8 of which are programmed by nuclear DNA; complex IV (cytochrome-c-oxidase) has 13 subunits, only 3 of which are encoded by mtDNA. For this reason, mitochondrial diseases of muscle may be transmitted as autosomal recessive traits rather than by strict maternal transmission even though all mitochondria are inherited from the mother.

In the Kearns-Sayre syndrome, a single large mtDNA deletion has been identified, but other genetic variants are known; in the MERRF and MELAS syndrome*s* of mitochondrial myopathy, point mutations occur in tRNA (see Table 599–1).

There is no effective treatment of mitochondrial cytopathies, but various “cocktails” are often used empirically to try to overcome the metabolic deficits. These include oral carnitine supplements, riboflavin, coenzyme Q_{10} , ascorbic acid (vitamin C), vitamin E, and other antioxidants. Although some anecdotal reports are encouraging, no controlled studies that prove efficacy are published.

602.5 Lipid Myopathies

(See Chapter 75.4 .)

Considered as metabolic organs, skeletal muscles are the most important sites in the body for long-chain fatty acid metabolism because of their large mass and their rich density of mitochondria where fatty acids are metabolized. Hereditary disorders of lipid metabolism that cause progressive myopathy are an important, relatively common, and often treatable group of muscle diseases.

Muscle carnitine deficiency is an autosomal recessive disease involving deficient transport of dietary carnitine across the intestinal mucosa. Carnitine is acquired from dietary sources but is also synthesized in the liver and kidneys from lysine and methionine; it is the obligatory carrier of long- and medium-chain fatty acids into muscle mitochondria.

The clinical course may be one of sudden exacerbations of weakness or may resemble a progressive muscular dystrophy with generalized proximal myopathy and sometimes facial, pharyngeal, and cardiac involvement. Symptoms usually begin in late childhood or adolescence or may be delayed until adult life. Progression is slow but may end in death.

Serum CK level is mildly elevated. Muscle biopsy material shows vacuoles filled with lipid within muscle fibers in addition to nonspecific changes suggestive of a muscular dystrophy. Mitochondria may appear normal or abnormal. Carnitine measured in muscle biopsy tissue is reduced, but serum carnitine level is normal.

Treatment stops the progression of the disease and may even restore lost strength if the disease is not too advanced. It consists of special diets low in long-chain fatty acids. Steroids may enhance fatty acid transport. Specific therapy with L-carnitine taken orally in large doses overcomes the intestinal barrier in some patients. Some patients also improve when given supplementary riboflavin, and other patients seem to improve with propranolol.

Systemic carnitine deficiency is a disease of impaired renal and hepatic synthesis of carnitine rather than a primary myopathy. Patients with this autosomal recessive disease experience progressive proximal myopathy and show muscle biopsy changes similar to those of muscle carnitine deficiency; however, the onset of weakness is earlier and may be evident at birth. Endocardial fibroelastosis also may occur. Episodes of acute hepatic encephalopathy resembling Reye syndrome may occur. Hypoglycemia and metabolic acidosis complicate acute episodes.

The concentration of carnitine is reduced in serum as well as in muscle and liver. A similar clinical syndrome may be a complication of renal Fanconi syndrome, because of excessive urinary loss of carnitine or loss during chronic hemodialysis.

Treatment with L-carnitine improves the maintenance of blood glucose and serum carnitine levels but does not reverse the ketosis or acidosis or improve exercise capacity.

Muscle carnitine palmitoyltransferase (CPT) deficiency presents as episodes of rhabdomyolysis, coma, and elevated serum CK level that may be indistinguishable from Reye syndrome. CPT transfers long-chain fatty acid acyl-CoA residues to carnitine on the outer mitochondrial membrane for transport into the mitochondria. Exercise intolerance and myoglobinuria resemble glycogenoses V and VII. Fasting hypoglycemia may also occur. Genetic transmission is autosomal recessive, owing to a defect on chromosome 1 at the 1p32 locus. Administration of valproic acid may precipitate acute rhabdomyolysis with myoglobinuria in patients with CPT deficiency; it should be avoided in the treatment of seizures or migraine if they occur.

602.6 Vitamin E Deficiency Myopathy

Deficiency of vitamin E (a-tocopherol; an antioxidant also important in mitochondrial superoxide generation) in experimental animals produces a progressive myopathy closely resembling a muscular dystrophy. Myopathy and neuropathy are recognized in humans who lack adequate intake of this antioxidant. Patients with chronic malabsorption, those undergoing long-term dialysis, and premature infants who do not receive vitamin E supplements are particularly vulnerable. Treatment with high doses of vitamin E may reverse the deficiency. Myopathy due to chronic hypervitaminosis E also occurs.

Chapter 603 - Disorders of Neuromuscular Transmission and of Motor Neurons

603.1 Myasthenia Gravis

Myasthenia gravis is a disease caused by an immune-mediated neuromuscular blockade. The release of acetylcholine (ACh) into the synaptic cleft by the axonal terminal is normal, but the postsynaptic muscle membrane or *motor end plate* is less responsive than normal. A decreased number of available ACh receptors is due to circulating receptor-binding antibodies in most cases of acquired myasthenia. The disease is generally nonhereditary and is an autoimmune disorder. A rare familial myasthenia gravis is probably an autosomal recessive trait and is not associated with plasma anti-ACh antibodies. One familial form is a deficiency of motor end plate ACh, designated AChE. Infants born to myasthenic mothers may have a transient neonatal myasthenic syndrome secondary to placentally transferred anti-ACh receptor antibodies, distinct from congenital myasthenia gravis.

Clinical Manifestations.

Ptosis and some degree of extraocular muscle weakness are the earliest and most constant signs in

myasthenia gravis. Older children may complain of diplopia, and young children may hold open their eyes with their fingers or thumbs if the ptosis is severe enough to obstruct vision. The pupillary responses to light are preserved. Dysphagia and facial weakness are also common, and in early infancy feeding difficulties are often the cardinal sign of myasthenia. Poor head control because of weakness of the neck flexors is also prominent. Involvement may be limited to bulbar-innervated muscles, but the disease is systemic and weakness involves limb-girdle muscles and distal muscles of the hands in most cases. Fasciculations of muscle, myalgias, and sensory symptoms do not occur. Tendon stretch reflexes may be diminished but are rarely lost.

Rapid fatigue of muscles is a characteristic feature of myasthenia gravis that distinguishes it from most other neuromuscular diseases. Ptosis increases progressively as patients are asked to sustain an upward gaze for 30–90?sec. Holding the head up from the surface of the examining table while lying supine is very difficult, and gravity cannot be overcome for more than a few seconds. Repetitive opening and closing of the fists produces rapid fatigue of hand muscles, and patients cannot elevate their arms for more than 1–2?min because of fatigue of the deltoids. Patients are more symptomatic late in the day or when tired. Dysphagia may interfere with eating, and the muscles of the jaw soon tire when an affected child chews.

If untreated, myasthenia gravis is usually progressive and may become life threatening because of respiratory muscle involvement and the risk of aspiration, particularly at times when the child is otherwise unwell with an upper respiratory tract infection. Familial myasthenia gravis usually is not progressive.

Infants born to myasthenic mothers may have respiratory insufficiency, inability to suck or swallow, and generalized hypotonia and weakness. They may show little spontaneous motor activity for several days to weeks. Some require ventilatory support and feeding by gavage during this period. After the abnormal antibodies disappear, the infants have normal strength and are not at increased risk for developing myasthenia gravis in later childhood. The syndrome of *transient neonatal myasthenia gravis* is to be distinguished from a rare and often hereditary *congenital myasthenia gravis* not related to maternal myasthenia that is nearly always a permanent disorder without spontaneous remission. Three presynaptic congenital myasthenic syndromes are recognized, all as autosomal recessive traits, but their molecular genetic basis remains unknown. Another synaptic form is caused by absence or marked deficiency of AChE in the synaptic basal lamina, and postsynaptic forms of congenital myasthenia are caused by mutations in AChR (acetylcholine receptor) subunit genes that alter the synaptic response to ACh. An abnormality of the ACh receptor channels appearing as high conductance and excessively fast closure may be the result of a point mutation in a subunit of the receptor affecting a single amino acid residue. Children with congenital myasthenia gravis do not experience myasthenic crises and rarely exhibit elevations of anti-ACh antibodies in plasma.

Myasthenia gravis is occasionally secondary to hypothyroidism, usually due to *Hashimoto thyroiditis*. Other collagen vascular diseases may also be associated. Thymomas, noted in some adults, rarely coexist with myasthenia gravis in children; nor do carcinomas of the lung occur, which produce a unique form of myasthenia in adults, the *Eaton-Lambert syndrome*.

Laboratory Findings and Diagnosis.

Myasthenia gravis is one of the few neuromuscular diseases in which an *electromyogram* (EMG) is more specifically diagnostic than a muscle biopsy. A decremental response is seen in response to repetitive nerve stimulation; the muscle potentials diminish rapidly in amplitude until the muscle becomes refractory to further stimulation. Motor nerve conduction velocity remains normal. This unique EMG pattern is the electrophysiologic correlate of the fatigable weakness observed clinically and is reversed after a cholinesterase inhibitor is administered. A myasthenic decrement may be absent or difficult to demonstrate in muscles that are not involved clinically. This feature may be confusing in early cases or in patients showing only weakness of extraocular muscles. Microelectrode studies of end plate potentials and currents reveal whether the transmission defect is presynaptic or postsynaptic. Special electrophysiologic studies are required in the classification of

congenital myasthenic syndromes and involve the estimation of the number of AChR per end-plate and in vitro study of end plate function. These special studies and patch-clamp recordings of kinetic properties of channels are performed on special biopsies of intercostal muscle strips that include both origin and insertion of the muscle but are only performed in specialized centers.

Anti-ACh antibodies should be assayed in the plasma but are inconsistently demonstrated. About one third of adolescents show elevations, but anti-ACh receptor antibodies are only occasionally demonstrated in the plasma of prepubertal children. Other serologic tests of autoimmune disease, such as antinuclear antibodies and abnormal immune complexes, should also be sought. If these are positive, more extensive autoimmune disease involving vasculitis or tissues other than muscle is likely. A thyroid profile should always be examined. The serum creatine kinase (CK) level is normal in myasthenia gravis.

The heart is not involved, and the electrocardiogram (ECG) findings remain normal. Roentgenograms of the chest often reveal an enlarged thymus, but the hypertrophy is not a *thymoma*. It may be further defined by tomography or by CT scanning of the anterior mediastinum.

The role of conventional *muscle biopsy* in myasthenia gravis is limited. It is not required in most cases, but about 17% of patients show inflammatory changes sometimes called *lymphorrhages* that are interpreted by some physicians as a mixed myasthenia-polymyositis immune disorder. Muscle biopsy tissue in myasthenia gravis shows nonspecific type II muscle fiber atrophy, similar to that seen with disuse atrophy, steroid effects on muscle, polymyalgia rheumatica, and many other conditions. The ultrastructure of motor end plates shows simplification of the membrane folds.

A *clinical test for myasthenia gravis* is administration of a short-acting cholinesterase inhibitor, usually edrophonium chloride. Ptosis and ophthalmoplegia improve within a few seconds, and fatigability of other muscles decreases.

RECOMMENDATIONS ON THE USE OF CHOLINESTERASE INHIBITORS AS A DIAGNOSTIC TEST FOR MYASTHENIA GRAVIS IN INFANTS AND CHILDREN

For Children 2 Yr of Age or Older

1. Child should have a specific fatigable weakness that can be measured, such as ptosis of the eyelids, dysphagia, inability of cervical muscles to support head; nonspecific generalized weakness without cranial nerve motor deficits is not a criterion.
2. An intravenous infusion should be started to enable the administration of medications in the event of an adverse reaction.
3. ECG monitoring during test is recommended.
4. A dose of atropine sulfate (0.01?mg/kg) should be available in a syringe, ready for intravenous administration at the bedside during the edrophonium test, to block acute muscarinic effects of the cholinesterase inhibitor (mainly abdominal cramps and/or sudden diarrhea from increased peristalsis, profuse bronchotracheal secretions that may obstruct the airway, or, rarely, cardiac arrhythmias, if needed. Some physicians pretreat all patients with atropine before administering edrophonium, but this is not recommended unless there is a history of reaction from previous tests. Remember that atropine may cause the pupils to be dilated and fixed for as long as 14 days after a single dose, and the pupillary effects of homatropine may last 4–7 days.

5. Edrophonium chloride (Tensilon) is administered intravenously. Initially, a test dose of 0.04?mg/kg is given to ensure that the patient does not have an allergic reaction or is otherwise very sensitive to muscarinic side effects. If this test dose is well tolerated, the diagnostic dose administered is 0.1 to 0.2?mg/kg (maximum single dose 10?mg, regardless of weight; in children weighing less than 30?kg, 2?mg is the maximum dose; a typical dose for a 3–5-yr-old child is 5?mg). These same doses may be given intramuscularly or subcutaneously, but these routes are not recommended because the results are much more variable because of unpredictable absorption, and the test may be ambiguous or falsely negative.
6. Effects should be seen within 10 seconds and disappear within 120 seconds; weakness is measured (e.g., distance between upper and lower eyelids before and after administration; degree of external ophthalmoplegia; ability to swallow a sip of water).
7. Long-acting cholinesterase inhibitors, such as pyridostigmine (Mestinon) are generally not as useful for the acute assessment of myasthenic weakness. The prostigmine test may be used (as outlined later) but may not be as definitively diagnostic as the edrophonium test.

For Infants Younger than 2 Yr of Age

1. Infant ideally should have a specific fatigable weakness that can be measured, such as ptosis of the eyelids, dysphagia, inability of cervical muscles to support head; nonspecific generalized weakness without cranial nerve motor deficits is less easy to assess results but may be a criterion at times.
2. An intravenous infusion should be started as a rapid route for medications in the event of an adverse effect of the test medication.
3. ECG monitoring is recommended during test.
4. Pretreatment with atropine sulfate to block the muscarinic effects of the test medication is not recommended but should be available at the bedside in a prepared syringe. If needed, it should be administered intravenously in a dose of 0.1?mg/kg.
5. Edrophonium is not recommended for use in infants; its effect is too brief for objective assessment and an increased incidence of acute cardiac arrhythmias is reported in infants, especially neonates, with this drug.
6. Prostigmine methylsulfate (Neostigmine) is administered intramuscularly at a dose of 0.04?mg/kg; if the result is negative or equivocal, another dose of 0.04?mg/kg may be administered 4 hours after the first dose (a typical dose is 0.5–1.5?mg). The peak effect is seen in 20–40 minutes. Intravenous prostigmine is not recommended because of risk of cardiac arrhythmias.
7. Long-acting cholinesterase inhibitors administered orally, such as pyridostigmine (Mestinon), are generally not as useful for the acute assessment of myasthenic weakness because onset and duration are less predictable.

WHERE SHOULD TEST BE PERFORMED?

The setting may be the emergency department, hospital ward, or, at times, a physician's office; the important issue is preparation for potential complications such as cardiac arrhythmia or cholinergic crisis, as previously outlined.

Treatment.

Some patients with mild myasthenia gravis require no treatment. *Cholinesterase-inhibiting drugs* are the primary therapeutic agents. Neostigmine methylsulfate (0.04?mg/kg) may be given intramuscularly every 4–6?hr, but most patients tolerate oral neostigmine bromide, 0.4?mg/kg every 4–6?hr. If dysphagia is a major problem, the drug should be given about 30?min before meals to improve swallowing. Pyridostigmine is an alternative; the dose required is about four times greater than that of neostigmine, but it may be slightly longer acting. Overdoses of cholinesterase inhibitors produce cholinergic crises; atropine blocks the muscarinic effects but does not block the nicotinic effects that produce additional skeletal muscle weakness. In the rare familial myasthenia gravis caused by absence of end-plate AChE, cholinesterase inhibitors are not helpful and often cause increased weakness; these patients can be treated with ephedrine or with an experimental drug, diaminopyridine (DAP), both of which increase ACh release from terminal axons.

Because of the autoimmune basis of the disease, long-term *steroid treatment* with prednisone may be effective. *Thymectomy* should be considered and may provide a cure. Thymectomy is most effective in patients with high titers of anti-ACh-receptor antibodies in the plasma and who are symptomatic for less than 2 yr. Thymectomy is ineffective in congenital and familial forms of myasthenia gravis. Treatment of hypothyroidism usually abolishes an associated myasthenia without the use of cholinesterase inhibitors or steroids.

Plasmapheresis is effective treatment in some children, particularly those who do not respond to steroids, but plasma exchange therapy may provide only temporary remission. *Intravenous immunoglobulin* (IVIG) is sometimes beneficial and might be tried before plasmapheresis because it is less invasive. Both plasmapheresis and IVIG appear to be most effective in patients with high circulating levels of anti-ACh receptor antibodies.

Neonates with transient maternally transmitted myasthenia gravis require cholinesterase inhibitors for only a few days or occasionally for a few weeks, especially to allow feeding. No other treatment is usually necessary.

Complications.

Children with myasthenia gravis do not tolerate neuromuscular blocking drugs, such as succinylcholine and pancuronium, and may be paralyzed for weeks after a single dose. An anesthesiologist should carefully review myasthenic patients who require a surgical anesthetic. Also, certain antibiotics may potentiate myasthenia and should be avoided; these include the aminoglycosides (gentamicin and others).

Prognosis.

This is difficult to predict. Some patients undergo spontaneous remission after a period of months or years; others have a permanent disease extending into adult life. Immunosuppression, thymectomy, and treatment of associated hypothyroidism may provide a cure.

OTHER CAUSES OF NEUROMUSCULAR BLOCKADE

Organophosphate chemicals, commonly used as insecticides, may cause a myasthenia-like syndrome in children exposed to these toxins (see Chapter 704).

Botulism results from ingestion of food containing the toxin of *Clostridium botulinum*, a gram-positive, spore-bearing, anaerobic bacillus (see Chapter 193). Honey is a frequent source of contamination. The incubation period is short, only a few hours, and symptoms begin with nausea, vomiting, and diarrhea. Cranial nerve involvement soon follows, with diplopia, dysphagia, weak suck, facial weakness, and absent gag reflex. Generalized hypotonia and weakness then develop and may progress to respiratory failure. Neuromuscular blockade is documented by EMG with repetitive nerve stimulation. Respiratory support may be required for days or weeks until the toxin is cleared from the body. No specific antitoxin is available. Guanidine, 35?mg/kg/24?hr, may be effective for extraocular and limb muscle weakness but not for respiratory muscle involvement.

Tick paralysis is a disorder of ACh release from axonal terminals due to a neurotoxin that blocks depolarization. It also affects large myelinated motor and sensory nerve fibers. This toxin is produced by the wood tick or dog tick, insects common in the Appalachian and Rocky Mountains of North America. The tick embeds its head into the skin, usually the scalp, and neurotoxin production is maximal about 5–6 days later. Motor symptoms include weakness, loss of coordination, and sometimes an ascending paralysis resembling Guillain-Barré syndrome. Tendon reflexes are lost. Sensory symptoms of tingling

paresthesias may occur in the face and extremities. The diagnosis is confirmed by EMG and nerve conduction studies and by identifying the tick. The tick must be removed completely, and the buried head not left beneath the skin. Patients then recover completely within hours or days.

603.2 Spinal Muscular Atrophies

Spinal muscular atrophies (SMA) are degenerative diseases of motor neurons that begin in fetal life and continue to be progressive in infancy and childhood. The progressive denervation of muscle is compensated in part by re-innervation from an adjacent motor unit, but giant motor units are thus created with subsequent atrophy of muscle fibers when the re-innervating motor neuron eventually becomes involved. Upper motor neurons remain normal.

SMA is classified into a severe infantile form, also known as *Werdnig-Hoffmann disease* or SMA type 1; a late infantile and more slowly progressive form, SMA type 2; and a more chronic or juvenile form, also called *Kugelberg-Welander disease*, or SMA type 3. These distinctions are clinical and are based on age at onset, severity of weakness, and clinical course; muscle biopsy does not distinguish types 1 and 2, although type 3 shows a more adult than perinatal pattern of denervation/re-innervation. Some patients are transitional between types 1 and 2 or between types 2 and 3 in terms of clinical function. A variant of SMA, *Fazio-Londe disease*, is a progressive bulbar palsy resulting from motor neuron degeneration more in the brain stem than the spinal cord.

Etiology.

The cause of SMA is a pathologic continuation of a process of programmed cell death that is normal in embryonic life. A surplus of motor neuroblasts and other neurons is generated from primitive neuroectoderm, but only about half survive and mature to become neurons; the excess cells have a limited life cycle and degenerate. If the process that arrests physiologic cell death fails to intervene by a certain stage, neuronal death may continue in late fetal life and postnatally. The survivor motor neuron *(SMN)* gene arrests apoptosis (programmed cell death) of motor neuroblasts. Unlike most genes that are highly conserved in evolution, *SMN* is a unique mammalian gene.

Clinical Manifestations.

The cardinal features of SMA type 1 are severe hypotonia; generalized weakness; thin muscle mass; absent tendon stretch reflexes; involvement of the tongue, face, and jaw muscles; and sparing of extraocular muscles and sphincters. Infants who are symptomatic at birth may have respiratory distress and are unable to feed. Congenital contractures, ranging from simple clubfoot to generalized arthrogryposis, occur in about 10% of severely involved neonates. Infants lie flaccid with little movement, unable to overcome gravity. They lack head control. More than two thirds

die by 2 yr of age, and many die early in infancy.

In type 2 SMA, affected infants are usually able to suck and swallow and respiration is adequate in early infancy. These infants show progressive weakness, but many survive into the school years or beyond, although confined to an electric wheelchair and severely handicapped. Nasal speech and problems with deglutition develop later. Scoliosis becomes a major complication in many patients with long survival.

Kugelberg-Welander disease is the mildest SMA (type 3), and patients may appear normal in infancy. The progressive weakness is proximal in distribution, particularly involving shoulder girdle muscles. Patients are ambulatory. Symptoms of bulbar muscle weakness are rare. About 25% of patients with this form of SMA have muscular hypertrophy rather than atrophy, and it may easily be confused with a muscular dystrophy. Longevity may extend well into middle adult life. Fasciculations are a specific clinical sign of denervation of muscle. In thin children, they may be seen in the deltoid, biceps brachii, and occasionally the quadriceps femoris, but the continuous involuntary wormlike movements may be masked by a thick pad of subcutaneous fat. Fasciculations are best observed in the tongue, where almost no subcutaneous connective tissue separates the muscular layer from the epithelium. If the intrinsic lingual muscles are contracted, such as in crying or when the tongue protrudes, fasciculations are more difficult to see than when the tongue is relaxed.

The outstretched fingers of children with SMA often show a characteristic tremor owing to fasciculations and weakness. It should not be confused with a cerebellar tremor. Myalgias are not a feature of SMA.

The heart is not involved in SMA. Intelligence is normal, and children often appear brighter than their normal peers because the effort they cannot put into physical activities is redirected to intellectual development, and they are often exposed to adult speech more than to juvenile language because of the social repercussions of the disease.

Laboratory Findings.

The serum CK level may be normal but more commonly is mildly elevated in the hundreds. A CK level of several thousand is rare. Results of motor nerve conduction studies are normal, except for mild slowing in terminal stages of the disease, an important feature distinguishing SMA from peripheral neuropathy. The EMG shows fibrillation potentials and other signs of denervation of muscle.

Diagnosis.

The simplest, most definitive diagnostic test is a molecular genetic marker in blood for the *SMN* gene. Muscle biopsy reveals a characteristic pattern of perinatal denervation that is unlike that of mature muscle. Groups of giant type I fibers are mixed with fascicles of severely atrophic fibers of both histochemical types (Fig. 603–1). Scattered immature myofibers resembling myotubes also are demonstrated. In juvenile SMA, the pattern may be more similar to adult muscle that has undergone many cycles of denervation and re-innervation. Neurogenic changes in muscle also may be demonstrated by EMG, but the results are less definitive than by muscle biopsy in infancy. Sural nerve biopsy sometimes shows mild sensory neuropathic changes, and sensory nerve conduction

Figure 603.2-1 Muscle biopsy of neonate with infantile spinal muscular atrophy. Groups of giant type I (darkly stained) fibers are seen within muscle fascicles of severely atrophic fibers of both histochemical types. This is the characteristic pattern of perinatal denervation of muscle. Myofibrillar ATPase, preincubated at pH 4.6. (×400.)

velocity may be slowed. At autopsy, mild degenerative changes are seen in sensory neurons of dorsal root ganglia and in somatosensory nuclei of the thalamus, but these alterations are not perceived clinically as sensory loss or paresthesias. The most pronounced neuropathologic lesions are the extensive neuronal degeneration and gliosis in the ventral horns of the spinal cord and brain stem motor nuclei, especially the hypoglossal nucleus.

Genetics.

Molecular genetic diagnosis by DNA probes in blood samples or in muscle biopsy or chorionic villi tissues is available not only for diagnosis of suspected cases but also for prenatal diagnosis. Most cases are inherited as an autosomal recessive trait. The incidence of SMA is 10–15 per 100,000 live births, affecting all ethnic groups; it is the second most common neuromuscular disease, following Duchenne muscular dystrophy. The incidence of heterozygosity for autosomal recessive SMA is 1:50. The genetic locus for all three of the common forms of SMA is on chromosome 5, a deletion at the 5q11-q13 locus, indicating that they are variants of the same disease rather than different diseases. The affected *SMN* gene contains 8 exons that span 20?kb, with telomeric and centromeric exons that differ only by 5?bp and produce a transcript encoding 294 amino acids. Another gene, the *neuronal apoptosis inhibitory gene (NAIP)* is located next to the *SMN* gene and in many cases there is an inverted duplication with two copies, telomeric and centromeric, of both genes; isolated mutations or deletions of *NAIP* do not produce clinical SMA.

Infrequent families with autosomal dominant inheritance are described, and a rare X-linked recessive form is reported. Carrier testing by dosage analysis is available.

Treatment.

No medical treatment is able to delay the progression. Supportive therapy includes orthopedic care with particular attention to scoliosis and joint contractures, mild physiotherapy, and mechanical aids for assisting the child to eat and to be as functionally independent as possible. Most children learn to use a computer keyboard with great skill but cannot use a pencil easily.

603.3 Other Motor Neuron Diseases

Motor neuron diseases other than SMA are rare in children. *Poliomyelitis* used to be a major cause of chronic disability, but since the routine use of polio vaccine, this viral infection is now rare (see Chapter 228). *Other enteroviruses*, such as Coxsackieviruses and Echoviruses, or the live polio vaccine virus, may also cause an acute infection of motor neurons with symptoms and signs similar to poliomyelitis, although usually milder. Specific polymerase chain reaction tests and viral cultures of cerebrospinal fluid are diagnostic.

A *juvenile form of amyotrophic lateral sclerosis* is rare. Upper motor neuron loss as well as lower motor neuron loss is evident clinically, unlike SMA. The course is progressive and is ultimately fatal.

The *Pena-Shokeir* and *Marden-Walker syndromes* are progressive motor neuron degenerations associated with severe arthrogryposis and congenital anomalies of many organ systems. *Pontocerebellar hypoplasias* are progressive degenerative diseases of the central nervous system that begin in fetal life; one form also involves motor neuron degeneration resembling a spinal muscular atrophy, but the *SMN* gene or chromosome 5 is normal.

Motor neurons become involved in several metabolic diseases of the nervous system, such as gangliosidosis (Tay-Sachs disease), ceroid lipofuscinosis (Batten disease), and glycogenosis II (Pompe disease), but the signs of denervation may be minor or obscured by the more prominent involvement of other parts of the central nervous system or of muscle.

Chapter 604 - Hereditary Motor-Sensory Neuropathies

The hereditary motor-sensory neuropathies (HMSN) are a group of progressive diseases of peripheral nerves. Motor components generally dominate the clinical picture, but sensory and autonomic involvement are expressed later.

604.1 Peroneal Muscular Atrophy (Charcot-Marie-Tooth Disease; HMSN Type I)

This disease is the most common genetically determined neuropathy and has an overall prevalence of 3.8/100,000. It is transmitted as an autosomal dominant trait with 83% expressivity; the 17p11.2 locus is the site of the abnormal gene. The gene product is *peripheral myelin protein P22* (PMP22). A much rarer X-linked HMSN type I results from a defect at the Xq13.l locus, causing mutations in the gap junction protein *connexin-32*.

Clinical Manifestations.

Most patients are asymptomatic until late childhood or early adolescence, but young children sometimes show signs of gait disturbance as early as the 2nd yr. The peroneal and tibial nerves are the earliest and most severely affected. Children with the disorder are often described as being clumsy, falling easily, or tripping over their own feet. The onset of symptoms may be delayed until after the 5th decade.

Muscles of the anterior compartment of the lower legs become wasted, and the legs have a characteristic storklike contour. The muscular atrophy is accompanied by progressive weakness of dorsiflexion of the ankle and eventual footdrop. The process is bilateral but may be slightly asymmetric. Pes cavus deformities may develop because of denervation of intrinsic foot muscles, further destabilizing the gait. Atrophy of muscles of the forearms and hands is usually not as severe as that of

the lower extremities, but in advanced cases contractures of the wrists and fingers produce a claw hand. Proximal muscle weakness is a late manifestation and is usually mild. Axial muscles are not involved.

The disease is slowly progressive throughout life, but patients occasionally show accelerated deterioration of function over a few years. Most patients remain ambulatory and have normal longevity, although orthotic appliances are required to stabilize the ankles.

Sensory involvement mainly affects large myelinated nerve fibers that convey proprioceptive information and vibratory sense, but the threshold for pain and temperature may also increase. Some children complain of tingling or burning sensations of the feet, but pain is rare. Because the muscle mass is reduced, the nerves are more vulnerable to trauma or compression. Autonomic manifestations may be expressed as poor vasomotor control with blotching or pallor of the skin of the feet and inappropriately cold feet.

Nerves often become palpably enlarged. Tendon stretch reflexes are lost distally. Cranial nerves are not affected. Sphincter control remains well preserved. Autonomic neuropathy does not affect the heart, gastrointestinal tract, or bladder. Intelligence is normal.

Davidenkow syndrome is a variant of HMSN type I with a scapuloperoneal distribution.

Laboratory Findings and Diagnosis.

Motor and sensory nerve conduction velocities are greatly reduced, sometimes as slow as 20% of normal conduction time. In new cases without a family history, both parents should be examined, and nerve conduction studies should be performed.

Electromyography (EMG) and muscle biopsy are not usually required for diagnosis, but they show evidence of many cycles of denervation and reinnervation. Serum creatine kinase (CK) level is normal. Cerebrospinal fluid (CSF) protein may be elevated, but no cells appear in the CSF.

Sural nerve biopsy is diagnostic. Large- and medium-sized myelinated fibers are reduced in number, collagen is increased, and characteristic *onion bulb formations* of proliferated Schwann cell cytoplasm surround axons. This pathologic finding is called *interstitial hypertrophic neuropathy*. Extensive segmental demyelination and remyelination also occur.

The definitive molecular genetic diagnosis may be made in blood.

Treatment.

Stabilization of the ankles is a primary concern. In early stages, stiff boots that extend to the mid-calf often suffice, particularly when patients walk on uneven surfaces such as ice and snow or stones. As the dorsiflexors of the ankles weaken further, lightweight plastic splints may be custom made to extend beneath the foot and around the back of the ankle. They are worn inside the socks and are not visible, reducing self-consciousness. External short-leg braces may be required when footdrop becomes complete. Surgical fusion of the ankle may be considered in some cases.

The leg should be protected from traumatic injury. In advanced cases, compression neuropathy during sleep may be prevented by placing soft pillows beneath or between the lower legs. Burning paresthesias of the feet are not common but are often abolished by phenytoin or carbamazepine. No medical treatment is available to arrest or slow the progression.

604.2 Peroneal Muscular Atrophy (Axonal Type)

This disease is clinically similar to HMSN type I, but the rate of progression is slower and the disability is less. EMG shows denervation of muscle. Sural nerve biopsy reveals axonal degeneration rather than the demyelination and whorls of Schwann cell processes typical in type I. The locus is on chromosome 1 at 1p35-p36; this is a different disease than HMSN type I, although both are transmitted as autosomal dominant traits.

604.3 Dejerine-Sottas Disease (HMSN Type III)

This interstitial hypertrophic neuropathy of autosomal dominant transmission is similar to HMSN type I but is more severe. Symptoms develop in early infancy and are rapidly progressive. Pupillary abnormalities, such as lack of reaction to light or *Argyll Robertson pupi*, are common. Kyphoscoliosis and pes cavus deformities complicate about 35% of cases. Nerves become palpably enlarged at an early age.

The onion-bulb formations seen in the sural nerve biopsy specimen are more pronounced. Hypomyelination also occurs.

The genetic locus of 17p11.2 is identical to that of HMSN type I or Charcot-Marie-Tooth disease. The clinical and pathologic differences may be phenotypic variants of the same disease, analogous to the situation in Duchenne and Becker muscular dystrophies. An autosomal recessive form of Dejerine-Sottas disease is also described but is incompletely documented.

604.4 Roussy-Lévy Syndrome

This syndrome is defined as a combination of HMSN type I and cerebellar deficit resembling Friedreich ataxia, but it does not have cardiomyopathy.

604.5 Refsum Disease

(See Chapter 75.2 .)

This rare disease is due to an enzymatic block in ß-oxidation of phytanic acid to pristanic acid. Phytanic acid is a branched-chain fatty acid that is derived mainly from dietary sources: spinach, nuts, and coffee. Levels of phytanic acid are greatly elevated in plasma, CSF, and brain tissue. The CSF shows an albuminocytologic dissociation with a protein concentration of 100–600?mg/dL.

Clinical onset is usually between 4 and 7 yr of age, with intermittent motor and sensory neuropathy. Ataxia, progressive neurosensory hearing loss, retinitis pigmentosa and loss of night vision, ichthyosis, and liver dysfunction also develop in various degrees. Motor and sensory nerve conduction velocities are delayed. Treatment is by dietary management and periodic plasma exchange.

604.6 Fabry Disease

(See Chapter 75.4 .)

This rare X-linked recessive trait results in storage of *ceramide trihexose* because of deficiency of the enzyme *ceramide trihexosidase*, which cleaves the terminal galactose from ceramide trihexose (ceramide-glucose-galactose-galactose), resulting in tissue accumulation of this trihexose lipid in central nervous system (CNS) neurons, Schwann cells and perineurial cells, ganglion cells of the myenteric plexus, skin, kidneys, blood vessel endothelial and smooth muscle cells, heart, sweat glands, cornea, and bone marrow.

Clinical Manifestations.

The presentation is in late childhood or adolescence, with recurrent episodes of burning pain and paresthesias of the feet and lower legs so severe that patients

are unable to walk. These episodes are often precipitated by fever or by physical activity. Objective sensory and motor deficits are not demonstrated on neurologic examination, and reflexes are preserved. Characteristic skin lesions are seen in the perineal region, scrotum, buttocks, and periumbilical zone as flat or raised red-black telangiectases known as *angiokeratoma corporis diffusum*. Hypohidrosis may be present. Corneal opacities, cataracts, and necrosis of the femoral heads are inconstant features. The disease is progressive. Hypertension and renal failure are usually delayed until early adult life. Recurrent strokes result from vascular wall involvement. Death occurs in the 5th decade owing to cerebral infarction or renal failure.

Laboratory Findings.

Motor and sensory nerve conduction velocities are normal to only mildly slow, showing preservation of large myelinated nerve fibers. CSF protein is normal. Proteinuria is present early in the course.

Pathologic features are usually first detected in skin or sural nerve biopsy specimens. Crystalline glycosphingolipids appear as *zebra bodies* in lysosomes of endothelial cells, in smooth myocytes of arterioles, and in Schwann cells, best demonstrated by electron microscopy. Nerves show a selective loss of small myelinated fibers and relative preservation of large and medium-sized axons, contrasting to most axonal neuropathies in which large myelinated fibers are most involved.

Assay for the deficient enzyme may be performed from skin fibroblasts, leukocytes, and other tissues. This test permits detection of the asymptomatic female carrier state and provides a reliable means of prenatal diagnosis.

Treatment.

See Chapter 75.4 .

604.7 Giant Axonal Neuropathy

This rare autosomal recessive disease with onset in early childhood is a progressive mixed peripheral neuropathy and degeneration of central white matter, similar to the leukodystrophies. Ataxia and nystagmus are accompanied by signs of progressive peripheral neuropathy. Some affected children have frizzy hair, which microscopically shows variation in diameter of the shaft or may appear normal. Focal axonal enlargements are seen in both the peripheral nervous system and the CNS, but the myelin sheath is intact. The disease is a general proliferation of intermediate filaments, including neurofilaments in axons, glial filaments (i.e., Rosenthal fibers) in brain, cytokeratin in hair, and vimentin in Schwann cells and fibroblasts. A homozygous mutation in the *GAN* gene at 16q24 is responsible for defective synthesis of the protein gygaxonin.

604.8 Congenital Hypomyelinating Neuropathy

This disorder is a lack of normal myelination of motor and sensory peripheral nerves but not of CNS white matter. It is not a degeneration or loss of previously formed myelin, thus differentiating it from a leukodystrophy. Schwann cells are preserved, and axons are normal. Cases in siblings suggest autosomal recessive inheritance.

The condition is present from birth; hypotonia and developmental delay are the hallmark clinical findings. Many patients present clinically as having congenital insensitivity to pain. Cranial nerves are inconsistently involved, and respiratory distress and dysphagia are rare complications. Tendon reflexes are absent. Arthrogryposis is present at birth in at least half the cases. It is uncertain whether the condition is progressive; myelination of nerves proceeds at a slow rate and remains incomplete. Motor and sensory nerve conduction velocities are slow. The diagnosis is confirmed by sural nerve biopsy, which shows lack of myelination of large and small fibers and sometimes interstitial hypertrophic reactive changes. Muscle biopsy may show mild neurogenic atrophy but not the characteristic alterations of spinal muscular atrophy. No inflammation is demonstrated in muscle or nerve. Treatment is supportive.

604.9 Tomaculous Neuropathy

This hereditary neuropathy is characterized by redundant overproduction of myelin around each axon in an irregular segmental fashion so that tomaculous (i.e., sausage-shaped) bulges occur in the individual myelinated nerve fibers. The nerves are particularly prone to pressure palsies, and patients present with recurrent mononeuropathies secondary to minor trauma. It is transmitted as an autosomal dominant trait, and the locus has been identified at 17p11.2. Sural nerve biopsy is diagnostic, but special “teased fiber” preparations should be made to demonstrate the myelin abnormalities most clearly. The genetic defect is a deletion of exons in the *PMP22* gene. Treatment is supportive.

604.10 Leukodystrophies

Several hereditary degenerative diseases of white matter of the CNS also cause peripheral neuropathy. The most important are Krabbe disease (globoid cell leukodystrophy), metachromatic leukodystrophy, and adrenoleukodystrophy (see Chapter 75).

Chapter 605 - Toxic Neuropathies

Many *chemicals* (organophosphates), *toxins*, and *drugs* are capable of causing peripheral neuropathy. *Heavy metals* are well-known neurotoxins. Lead poisoning, especially if chronic, causes mainly a motor neuropathy selectively involving large nerves, such as the common peroneal, radial, or median nerves, a condition known as *mononeuritis multiplex* (see Chapter 703). Arsenic produces painful burning paresthesias and motor polyneuropathy. Exposure to industrial and agricultural chemicals is a less common cause of toxic neuropathy in children than in adults.

Antimetabolic and immunosuppressive drugs, such as vincristine, cisplatin, and taxol, produce polyneuropathies as complications

of chemotherapy for neoplasms. This “iatrogenic” cause is the most frequent etiology of toxic neuropathies in children. It is usually an axonal degeneration rather than primary demyelination, unlike autoimmune neuropathies such as Guillain-Barré syndrome.

Chronic uremia is associated with toxic neuropathy and myopathy. The neuropathy is caused by excessive levels of circulating parathyroid hormone. Reduction in serum parathyroid hormone levels is accompanied by clinical improvement and a return to normal of nerve conduction velocity.

Chapter 606 - Autonomic Neuropathies

606.1 Familial Dysautonomia

Familial dysautonomia (Riley-Day syndrome) is an autosomal recessive disorder that is common in Eastern European Jews, among whom the incidence is 1/10,000–20,000, and the carrier state is estimated to be 1%. It is rare in other ethnic groups. The defective gene is at the 9q31-q33 locus.

Pathology.

This disease of the peripheral nervous system is characterized pathologically by a reduced number of small unmyelinated nerve fibers that carry pain, temperature, and taste sensations and that mediate autonomic functions. Large myelinated afferent nerve fibers that relay impulses from muscle spindles and Golgi tendon organs are also deficient. The degree of demonstrable anatomic change in peripheral and especially autonomic nerves is variable. Fungiform papillae of the tongue (taste buds) are absent or reduced in number.

Clinical Manifestations.

The disease is expressed in infancy by poor sucking and swallowing. Aspiration pneumonia may occur. Feeding difficulties remain a major symptom throughout childhood. Vomiting crises may occur. Excessive sweating and blotchy erythema of the skin are common, especially at mealtime or when the child is excited. Breath-holding spells followed by syncope are common in the first 5 yr. As affected children become older, insensitivity to pain becomes evident and traumatic injuries are frequent. Corneal ulcerations are common. Newly erupting teeth cause tongue ulcerations. Walking is delayed or clumsy or appears ataxic because of poor sensory feedback from muscle spindles. The ataxia is probably related more to deficient muscle spindle feedback and to vestibular nerve dysfunction than to cerebellar involvement. Tendon stretch reflexes are absent. Scoliosis is a serious complication in the majority of patients and usually is progressive. Normal overflow tearing with crying does not normally develop until 2–3 mo of age but fails to develop after that time or is severely reduced in children with familial dysautonomia.

About 40% of patients have generalized major motor seizures, some of which are associated with acute hypoxia during breath-holding, some with extreme fevers, but most without an apparent precipitating event. Body temperature is poorly controlled; both hypothermia and extreme fevers occur. Intellectual function is usually impaired but is unrelated to epilepsy. Puberty is often delayed, especially in girls. Speech is

often slurred or nasal.

After 3 yr of age, autonomic crises begin, usually with attacks of cyclic vomiting lasting 24–72?hr or even several days. Retching and vomiting occur every 15–20?min and are associated with hypertension, profuse sweating, blotching of the skin, apprehension, and irritability. Prominent gastric distention may occur, causing abdominal pain and even respiratory distress. Hematemesis may complicate pernicious vomiting.

Allgrove syndrome is a clinical variant, involving alacrima, achalasia, autonomic dysfunction with orthostatic hypotension and altered heart rate variability, and sensorimotor polyneuropathy, usually presenting in adolescence. Cholinergic dysfunction may be demonstrated.

Laboratory Findings.

Electrocardiography discloses prolonged correcting QT intervals with lack of appropriate shortening with exercise, a reflection of the aberration in autonomic regulation of cardiac conduction. Chest roentgenograms show atelectasis and pulmonary changes resembling cystic fibrosis. Urinary vanillylmandelic acid level is decreased, and homovanillic acid level is increased. Plasma level of dopamine ß-hydroxylase (the enzyme that converts dopamine to epinephrine) is diminished. Sural nerve biopsy shows a decreased number of unmyelinated fibers. An electroencephalogram is useful for evaluating seizures.

Diagnosis.

Slow intravenous infusion of norepinephrine produces an exaggerated pressor response. The hypotensive response to infusion of methacholine is increased. Intradermal injection of 1:1,000 histamine phosphate fails to produce a normal axon flare, and local pain is absent or diminished. Because the skin of a normal infant reacts more intensely to histamine, a 1:10,000 dilution should be used. Instillation of 2.5% methacholine into the conjunctival sac produces miosis in patients with familial dysautonomia and no detectable effect on a normal pupil; this is a nonspecific sign of parasympathetic denervation due to any cause. Methacholine is applied to only one eye in this test, with the other eye serving as a control; the pupils are compared at 5-min intervals for 20?min.

Treatment.

Symptomatic treatment includes special attention to the respiratory and gastrointestinal systems, methylcellulose eye drops or topical ocular lubricants to replace tears and prevent corneal ulceration, orthopedic management of scoliosis and joint problems, and appropriate anticonvulsants for epilepsy. Chlorpromazine is an effective antiemetic and may be given as rectal suppositories during autonomic crises. It also reduces apprehension and lowers the blood pressure. Dehydration and electrolyte disturbances should be anticipated. Bethanechol may be an alternative drug for cyclic vomiting. It is also useful for enuresis, another common complication, and augments tear production. Protection from injuries is important because of the lack of pain as a protective mechanism. Scoliosis often requires surgical treatment.

Intravenous gamma globulin results in dramatic improvement in the hypotension and pupillary areflexia in some cases and may deserve a clinical trial in severely disabled children, but most patients would be expected to have little benefit.

Prognosis.

Most patients die in childhood, usually of chronic pulmonary failure or aspiration.

606.2 Other Autonomic Neuropathies

Myenteric Plexus Neuropathies.

Aganglionic megacolon (Hirschsprung disease) is a failure of embryonic development of parasympathetic neurons in the submucosal and myenteric plexuses of segments of the colon and rectum. Nerves between the longitudinal and circular layers of smooth muscle of the gut wall are hypertrophic; ganglion cells are absent (see Chapter 313.3).

Congenital Insensitivity to Pain and Anhidrosis.

This hereditary disorder of uncertain genetic transmission affects boys much more frequently than girls and presents in early infancy. Patients have episodes of high fever related to warm environmental temperatures because they do not perspire. Frequent burns and traumatic injuries result from apparent lack of pain perception. Intelligence is normal. Nerve biopsy reveals an almost total absence of unmyelinated nerve fibers that convey impulses of pain, temperature, and autonomic functions. Some cases of hypomyelinating neuropathy present clinically as congenital insensitivity to pain (see Chapter 604.8). The sympathetic skin response as an electrophysiologic study is a reliable diagnostic test in cases associated with a mutation at the TrKA receptor for nerve growth factor (NGF).

Reflex Sympathetic Dystrophy.

This disorder is a form of local causalgia, usually involving a hand or foot but not corresponding to the anatomic distribution of a peripheral nerve. A continuous burning pain and hyperesthesia are associated with vasomotor instability in the affected zone, resulting in increased skin temperature, erythema, and edema due to vasodilatation and hyperhidrosis. In the chronic state, atrophy of skin appendages, cool and clammy skin, and disuse atrophy of underlying muscle and bone occur. More than one extremity is occasionally involved. The pain is disabling and is exacerbated by the movement of an associated joint, although no objective signs of arthritis are seen; immobilization provides some relief. The most common preceding event is local trauma in the form of a contusion, laceration, sprain, or fracture that occurred days or weeks earlier.

Several theories of pathogenesis have been proposed to explain this phenomenon. The most widely accepted is reflexive overactivity of autonomic nerves in response to injury, and regional sympathetic blockade often affords temporary relief. Physiotherapy also is helpful. Some cases resolve spontaneously after weeks or months, but others continue to be symptomatic and require sympathectomy. A psychogenic component is suspected in some cases but is difficult to prove.

Chapter 607 - Guillain-Barré Syndrome

Guillain-Barré syndrome is a postinfectious polyneuropathy involving mainly motor but sometimes also sensory and autonomic nerves. This syndrome affects people of all ages and is not hereditary. The disorder closely resembles experimental allergic polyneuritis in animals. Most patients have a demyelinating neuropathy, but primarily axonal degeneration is documented in some cases.

Clinical Manifestations.

The paralysis usually follows a nonspecific viral infection by about 10 days. The original infection may have caused only gastrointestinal (especially *Campylobacter jejuni*) or respiratory tract (especially *Mycoplasma pneumoniae*) symptoms. Weakness begins usually in the lower extremities and progressively involves the trunk, the upper limbs, and finally the bulbar muscles, a pattern known as **Landry ascending paralysis**. Proximal and distal muscles are involved relatively symmetrically, but asymmetry is found in 9% of patients. The onset is gradual and progresses over days or weeks. Particularly in cases with an abrupt onset, tenderness on palpation and pain in muscles is common in the initial stages. Affected children are irritable. Weakness may progress to inability or refusal to walk and later to flaccid tetraplegia. Paresthesias occur in some cases.

Bulbar involvement occurs in about half of cases. Respiratory insufficiency may result. Dysphagia and facial weakness are often impending signs of respiratory failure. They interfere with eating and increase the risk of aspiration. The facial nerves may be involved. Some young patients may exhibit symptoms of viral meningitis or meningoencephalitis. Extraocular muscle involvement is rare, but in an uncommon variant, oculomotor and other cranial neuropathies are severe early in the course. **The Miller-Fisher syndrome** consists of acute external ophthalmoplegia, ataxia, and areflexia. Papilledema is found in some cases, although visual impairment is not clinically evident. Urinary incontinence or retention of urine is a complication in about 20% of cases but is usually transient. The Miller-Fisher syndrome overlaps with Bickerstaff brainstem encephalitis, which also shares many features with Guillain-Barré syndrome with lower motor neuron involvement and may indeed be the same basic disease.

Tendon reflexes are lost, usually early in the course, but are sometimes preserved until later. This variability may cause confusion when attempting early diagnosis. The autonomic nervous system may also be involved in some cases. Lability of blood pressure and cardiac rate, postural hypotension, episodes of profound bradycardia, and occasional asystole occur. Cardiovascular monitoring is important. A few patients require insertion of a temporary venous cardiac pacemaker.

Prognosis.

The clinical course is usually benign, and spontaneous recovery begins within 2–3 wk. Most patients regain full muscular strength, although some are left with residual weakness. The tendon reflexes are usually the last function to recover. Improvement usually follows a gradient inverse to the direction of involvement, with recovery of bulbar function first and lower extremity weakness resolving last. Bulbar and respiratory muscle involvement may lead to death if the syndrome is not recognized and treated. Although prognosis is generally good with the majority of children recovering completely, three clinical features are predictive of poor outcome with sequelae: cranial nerve involvement, intubation, and maximum disability at the time of presentation. An electrophysiologic feature of conduction block, by contrast, is predictive of good outcome.

Chronic relapsing polyradiculoneuropathy (sometimes called chronic inflammatory demyelinating polyradiculoneuropathy) or *chronic unremitting polyradiculoneuropathy* are chronic varieties of Guillain-Barré syndrome that recur intermittently or do not improve for a period of months or years. About 7% of children with Guillain-Barré syndrome suffer relapse. Patients are usually severely weak and may have a flaccid tetraplegia with or without bulbar and respiratory muscle involvement.

Congenital Guillain-Barré syndrome is described rarely, presenting as generalized hypotonia, weakness, and areflexia in an affected neonate, fulfilling all electrophysiologic and cerebrospinal fluid (CSF) criteria, and in the absence of maternal

neuromuscular disease. Treatment may not be required, and there is gradual improvement over the first few months and no evidence of residual disease by a year of age. In one case, the mother had ulcerative colitis treated with prednisone and mesalamine from the 7th month until delivery at term.

Laboratory Findings and Diagnosis.

CSF studies are essential for diagnosis. The CSF protein is elevated to more than twice the upper limit of normal, glucose level is normal, and there is no pleocytosis. Fewer than 10 white blood cells/mm^3 are found. The results of bacterial cultures are negative, and viral cultures rarely isolate specific viruses. The dissociation between high CSF protein and a lack of cellular response in a patient with an acute or subacute polyneuropathy is diagnostic of Guillain-Barré syndrome.

Motor nerve conduction velocities are greatly reduced, and sensory nerve conduction time is often slow. An electromyogram shows evidence of acute denervation of muscle. Serum creatine phosphokinase (CK) level may be mildly elevated or normal. Antiganglioside antibodies, mainly against GM1 and GD1, are sometimes elevated in the serum in Guillain-Barré syndrome, particularly in cases with primarily axonal

rather than demyelinating neuropathy, and suggest that they may play a role in disease propagation and/or recovery in some cases. Muscle biopsy is not usually required for diagnosis; specimens appear normal in early stages and show evidence of denervation atrophy in chronic stages. Sural nerve biopsy tissue shows segmental demyelination, focal inflammation, and wallerian degeneration but also is usually not required for diagnosis.

Serologic testing for *Campylobacter* infection helps establish the cause if results are positive but does not alter the course of treatment. Results of stool cultures are rarely positive because the infection is self-limited and only occurs for about 3 days, and the neuropathy follows the acute gastroenteritis.

Treatment.

Patients in early stages of this *acute* disease should be admitted to the hospital for observation because the ascending paralysis may rapidly involve respiratory muscles during the next 24?hr. Patients with slow progression may simply be observed for stabilization and spontaneous remission without treatment. Rapidly progressive ascending paralysis is treated with intravenous immunoglobulin (IVIG), administered for 2, 3, or 5 days. Plasmapheresis, steroids, and/or immunosuppressive drugs are alternatives, if IVIG is ineffective. Combined administration of immunoglobulin and interferon is effective in some patients. Supportive care, such as respiratory support, prevention of decubiti in children with flaccid tetraplegia, and treatment of secondary bacterial infections, is important.

Chronic relapsing polyradiculoneuropathy or unremitting chronic neuropathy is also treated with IVIG. Plasma exchange, sometimes requiring as many as 10 exchanges daily, is an alternative. Remission in these cases may be sustained, but relapses may occur within days, weeks, or even after many months; relapses usually respond to another course of plasmapheresis. Steroid and immunosuppressive drugs are another alternative, but their effectiveness is less predictable. High-dose pulsed methylprednisolone given intravenously is successful in some cases. The prognosis in chronic forms of the Guillain-Barré syndrome is more guarded than in the acute form, and many patients are left with major residual handicaps.

Even if *Campylobacter jejuni* infection is documented by stool culture or serologic tests, treatment of the infection is not necessary because it is self-limited, and the use of antibiotics does not alter the course of the polyneuropathy.

Chapter 608 - Bell Palsy

Bell palsy is an acute unilateral facial nerve palsy that is not associated with other cranial neuropathies or brainstem dysfunction. It is a common disorder at all ages from infancy through adolescence and usually develops abruptly about 2 wk after a systemic viral infection. The preceding infection is due to the Epstein-Barr virus in about 20% of cases; Lyme disease, herpes simplex virus, and mumps virus are identified in many others. The disease is believed to be a postinfectious allergic or immune demyelinating facial neuritis rather than an active viral invasion of the nerve or of its motor neurons of origin. At times, it is associated with hypertension.

Clinical Manifestations.

The upper and lower portions of the face are paretic, and the corner of the mouth droops. Patients are unable to close the eye on the involved side and may develop an exposure keratitis at night. Taste on the anterior two thirds of the tongue is lost on the involved side in about half of cases; this finding helps to establish the anatomic limits of the lesion as being proximal or distal to the chorda tympani branch of the facial nerve. Numbness and paresthesias do not occur.

Treatment.

Protection of the cornea with methylcellulose eye drops or an ocular lubricant is especially important at night. Studies do not support the efficacy of steroids to induce remission, and they are not recommended. Surgical decompression of the facial canal, theoretically to provide more space for the swollen facial nerve, is not of value.

Prognosis.

The prognosis is excellent. More than 85% of cases recover spontaneously with no residual facial weakness; another 10% have mild facial weakness as a sequela; only 5% are left with permanent severe facial weakness. In patients with chronic cases who do not recover within a few weeks, electrophysiologic examination of the facial nerve helps to determine the degree of neuropathy and regeneration. In chronic cases, other causes of facial neuropathy should be considered, including facial nerve tumors such as schwannomas and neurofibromas, infiltration of the facial nerve by leukemic cells or by a rhabdomyosarcoma of the middle ear, brainstem infarcts or tumors, and traumatic injury of the facial nerve.

Facial Palsy at Birth.

This is usually a compression neuropathy from forceps application during delivery and recovers spontaneously in a few days or weeks in most cases. Congenital Bell

palsy should not be diagnosed. *Congenital absence of the depressor angularis oris muscle* causes facial asymmetry, especially when an affected infant cries. It is not a facial nerve lesion but is a cosmetic defect that does not interfere with feeding. Infants with *Möbius syndrome* may have bilateral or, less commonly, unilateral facial palsy; this syndrome is usually caused by symmetric calcified infarcts in the tegmentum of the pons and medulla oblongata during midgestation or late fetal life, although it rarely may be a developmental anomaly of the brainstem. **REFERENCES**

Part 28 - Disorders of the Eye

Scott E. Olitsky
Leonard B. Nelson

Chapter 609 - Growth and Development

At birth, the eye of a normal full-term infant is approximately 65% of adult size. Postnatal growth is maximal during the 1st yr, proceeds at a rapid but decelerating rate until the 3rd yr, and continues at a slower rate thereafter until puberty, after which little change occurs. In general, the anterior structures of the eye are relatively large at birth but thereafter grow proportionately less than the posterior structures. This results in a progressive change in the shape of the globe; it becomes more spherical.

In an infant, the *sclera* is thin and translucent, with a bluish tinge. The *cornea* is relatively large in newborns (averaging 10?mm) and attains adult size (nearly 12?mm) by the age of 2 yr or earlier. Its curvature tends to flatten with age, with progressive change in the refractive properties of the eye. A normal cornea is perfectly clear. In infants born prematurely, the cornea may have a transient opalescent haze. The anterior chamber in a newborn appears shallow, and the angle structures, important in the maintenance of normal intraocular pressure, must undergo further differentiation after birth. The *iris*, typically light blue or gray at birth in white individuals, undergoes progressive change of color as the pigmentation of the stroma increases in the first 6 mo of life. The pupils of a newborn infant tend to be small and are often difficult to dilate. Remnants of the pupillary membrane (anterior vascular capsule) are often evident on ophthalmoscopic examination, appearing as cobweb-like lines crossing the pupillary aperture, especially in preterm infants.

The *lens* of a newborn infant is more spherical than that of an adult; its greater refractive power helps to compensate for the relative shortness of the young eye. The lens continues to grow throughout life; new fibers added to the periphery continually push older fibers toward the center of the lens. With age, the lens becomes progressively more dense and more resistant to change of shape during accommodation.

The *fundus* of a newborn's eye is less pigmented than that of an adult; the choroidal vascular pattern is highly visible, and the retinal pigmentary pattern often has a fine peppery or mottled appearance. In some darkly pigmented infants, the fundus has a gray or opalescent sheen. In a newborn, the macular landmarks, particularly the foveal light reflex, are less well defined and may not be readily apparent. The peripheral retina appears pale or grayish, and the peripheral retinal vasculature is immature, especially in premature infants. The optic nerve head color varies from pink to slightly pale, sometimes grayish. Within 4–6 mo, the appearance of the fundus approximates that of the mature eye.

Superficial retinal hemorrhages may be observed in many newborn infants. These are usually absorbed promptly and rarely leave any permanent effect. Conjunctival hemorrhages also may occur at birth and are resorbed spontaneously without consequence.

Remnants of the primitive hyaloid vascular system may also be seen as small tufts or wormlike structures projecting from the disc (Bergmeister papilla) or as a fine strand traversing the vitreous; in some cases, only a small dot (Mittendorf dot) remains on the posterior aspect of the lens capsule.

An infant's eye is somewhat hyperopic (farsighted). The general trend is for hyperopia to increase from birth until 7 yr. Thereafter, the level of hyperopia tends to decrease rapidly until age 14. Elimination of the hyperopic state may occur during this time. If the process continues, myopia (nearsightedness) develops. A slower continuation of the decrease in hyperopia, or increase in myopia, continues into the 3rd decade of life. The refractive state at any time in life depends on the net effect of many factors: the size of the eye, the state of the lens, and the curvature of the cornea.

Newborn infants tend to keep their eyes closed much of the time, but normal newborns can see, respond to changes in illumination, and fixate points of contrast. The *visual acuity* in newborns is estimated to be in the range of 20/400. One of the earliest responses to a formed visual stimulus is an infant's regard for the mother's face, evident especially during feeding. By 2 wk of age, an infant shows more sustained interest in large objects, and by 8–10 wk of age a normal infant can follow an object through an arc of 180 degrees. The acuity improves rapidly and may reach 20/30–20/20 by the age of 2–3 yr.

Many normal infants may have imperfect coordination of the *eye movements* and *alignment* during the early days and weeks, but proper coordination should be achieved by 3–6 mo, usually sooner. Persistent deviation of an eye in an infant requires evaluation.

Tears often are not present with crying until after 1–3 mo. Preterm infants have reduced reflex and basal tear secretion, which may allow topically applied medications to become concentrated and lead to rapid drying of their corneas.

Chapter 610 - Examination of the Eye

Examination of the eyes is a routine part of the periodic pediatric assessment beginning in the newborn period. The primary care physician is very important in detecting both obvious and insidious, asymptomatic eye diseases. Screening in schools and community programs can also be effective in detecting problems early. The American Academy of Ophthalmology recommends preschool vision screening as a means of reducing preventable visual loss (Table 610–1). This testing should be done by pediatricians during well child visits. Children should be examined by an ophthalmologist whenever a significant ocular abnormality or vision defect is noted or suspected. Children who are at high risk for ophthalmologic problems, such as genetically inherited ocular conditions and various systemic disorders, should also be examined by an ophthalmologist.

Basic examination, whether done by a pediatrician or an ophthalmologist, must include evaluation of visual acuity and the visual fields, assessment of the pupils, ocular motility and alignment, a general external examination, and an ophthalmoscopic examination of the media and fundi. When indicated, biomicroscopy (slit-lamp examination), cycloplegic refraction, and tonometry are performed by an ophthalmologist. Special diagnostic procedures, such as ultrasonic examination, fluorescein angiography, electroretinography, or visual evoked response (VER) testing, are also indicated for specific conditions.

Visual Acuity.

There are many tests of visual acuity. Which test is used depends on a child's age and ability to cooperate, as well as a clinician's preference and experience with each test. The most common visual acuity test in infants is an assessment of their ability to fixate and follow a target. If appropriate targets are used, this reflex can be demonstrated by about 6 wk of age. The test is performed by seating the child comfortably in the caretaker's lap. The object of visual interest, usually a bright-colored toy, is slowly moved to the right and to the left. The examiner observes whether the infant's eyes turn toward the object and follow its movements. The examiner can use a thumb to occlude one of the infant's eyes in order to test each eye separately. Although a sound-producing object might compromise the purity of the visual stimulus, in practice, toys that squeak or rattle heighten an infant's awareness and interest in the test.

The human face is a better target than test objects. The examiner can exploit this by

moving his or her face slowly in front of

TABLE 610-1 -- **Vision Screening Schedule for Infants and Children**

Age	Screening Test	Findings Requiring Referral
Newborn–3 mo	Red reflex test	Opacity of the cornea, cataract, retinal detachment or disorder
	Corneal light reflex test	Ocular misalignment (strabismus)
	External examination	Structural defect
6–12 mo	Red reflex test	As above
	Corneal light reflex test	As above
	Occlusion of each eye separately	Amblyopia if child resists occlusion unequally
	Fixation and following	Amblyopia if unable to do
3 yr	Red reflex test	As above
	Corneal light reflex test	As above
	Visual acuity test	Refractive error, amblyopia
	Stereoacuity	Refractive error, amblyopia
5 yr	Same as 3 yr	As above

From Catalano RA, Nelson LB: Pediatric Ophthalmology. A Text Atlas.Norwalk, CT, Appleton & Lange, 1994.

the infant's face. If the appropriate following movements are not elicited, the test should be repeated with the caretaker's face as the test stimulus. It should be remembered that even children with poor vision may follow a large object without apparent difficulty, especially if only one eye is affected.

An objective measurement of visual acuity is usually possible when children reach 2½–3 yr of age. Children this age are tested using a schematic picture or other illiterate eye chart. Each eye should be tested separately. It is essential to prevent peeking. The examiner should hold the occluder in place and observe the child throughout the test. The child should be reassured and encouraged throughout the test, because many children are intimidated by the procedure and fear a “bad grade” or punishment for errors.

The **E test,** in which a child points in the direction of the letter, is the most widely used visual acuity test for preschool children. Right-left presentations are more confusing than up-down presentations. With pretest practice, this test can be performed by most children 3–4 yr of age.

An adult-type **Snellen acuity chart** can be used at about 5 or 6 yr of age if the child knows letters. An acuity of 20/40 is generally accepted as normal for 3-yr-old children. At 4 yr of age, 20/30 is typical. By 5 or 6 yr of age, most children attain 20/20 vision.

Optokinetic nystagmus (the response to a sequence of moving targets; “railroad” nystagmus) can also be used to assess vision; this can be calibrated by targets of various sizes (stripes or dots) or by a rotating drum at specified distances. The visual evoked response (VER), an electrophysiologic method of evaluating the response to light and special visual stimuli, such as calibrated stripes or a checkerboard pattern, can also be used to study visual function in selected cases. Preferential looking tests are also used for evaluating vision in infants and children who cannot respond to standard acuity tests. This is a behavioral technique based on the observation that, given a choice, an infant prefers to look at patterned rather than unpatterned stimuli. Preferential looking tests cannot be directly correlated to standard visual acuity data. Because these tests require the presence of a skilled examiner, their use is often limited to research protocols involving preverbal children.

Visual Field Assessment.

Like visual acuity testing, visual field assessment must be geared to a child's age and abilities. Formal visual field examination (perimetry and scotometry) can often be accomplished in school-aged children. The examiner must often rely on confrontation techniques and finger counting in quadrants of the visual field. In many children, only testing by attraction can be accomplished; the examiner observes a child's response to familiar objects brought into each of the four quadrants of the visual field of each eye in turn. The child's bottle, a favorite toy, and lollipops are particularly effective attention-getting items. These gross methods can often detect diagnostically significant field changes such as the bitemporal hemianopia of a chiasmal lesion or the homonymous hemianopia of a cerebral lesion.

Color Vision Testing.

This can be accomplished whenever a child is able to name or trace the test symbols; these may be either numbers or X's, O's, triangles, or other symbols. Color vision testing is not frequently necessary in young children, but parents sometimes request it, particularly if their child seems to be slow in learning colors. Parents are often reassured to know that color “deficient” children do not misname colors and that true “color blindness” is very rare and not compatible with normal vision. Defective color vision is common in male patients but is rare in female patients. Achromatopsia, a total color vision defect with subnormal visual acuity, nystagmus, and photophobia, is encountered occasionally. A change in color discrimination can be a sign of optic nerve or retinal disease.

Pupillary Examination.

This includes evaluation of both the direct and consensual reactions to light, the reaction on near gaze, and the response to reduced illumination, noting the size and symmetry of the pupils under all conditions. Special care must be taken to differentiate the reaction to light from the reaction to near gaze. A child's natural tendency is to look directly at the approaching light, inducing the near gaze reflex

when one is attempting to test only the reaction to light; accordingly, every effort must be made to control fixation. The swinging flashlight test is especially useful for detecting unilateral or asymmetric prechiasmatic afferent defects in children (see Marcus Gunn Pupil, Chapter 613).

Ocular Motility.

This is tested by having a child follow an object into the various positions of gaze. Movements of each eye individually (ductions) and of the two eyes together (versions, conjugate movements, and convergence) are assessed. Alignment is judged by the symmetry of the corneal light reflexes and by the response to alternate occlusion of each eye (see discussion on cover tests for strabismus in Chapter 614).

Binocular Vision.

A determination of the degree of binocular vision is commonly performed by an ophthalmologist. The **Titmus test** is probably the most frequently used test; a series of three-dimensional images are shown to the child while he or she wears a set of Polaroid glasses. The level of difficulty with which these images can be detected correlates with the degree of binocular vision that is present. Other tests may also be used to detect the presence of abnormal binocular adaptations secondary to poor vision or strabismus.

External Examination.

This begins with general inspection in good illumination, noting size, shape, and symmetry of the orbits, position and movement of the lids, and position and symmetry of the globes. Viewing the eyes and lids from above aids in detecting orbital asymmetry, lid masses, proptosis (exophthalmos), and abnormal pulsations. Palpation is also important in detecting orbital and lid masses.

The lacrimal apparatus is assessed by looking for evidence of tear deficiency, overflow of tears (epiphora), erythema, and swelling in the region of the tear sac or gland. The sac is massaged to check for reflux when obstruction is suspected. The presence and position of the puncta are also checked.

The lids and conjunctiva are specifically examined for focal lesions, foreign bodies, and inflammatory signs; loss and maldirection of lashes should also be noted. When necessary, the lids can be everted in the following manner: (1) instruct the patient to look down; (2) grasp the lashes of the patient's upper lid between the thumb and index finger of one hand; (3) place a probe, a cotton-tipped applicator, or the thumb of the other hand at the upper margin of the tarsal plate; and (4) pulling the lid down and outward, evert it over the probe, using the instrument as a fulcrum. Foreign bodies commonly lodge in the concavity just above the lid margin and are exposed only by fully everting the lid.

The anterior segment of the eye is then evaluated with oblique focal illumination, noting luster and clarity of the cornea, depth and clarity of the anterior chamber, and features of the iris. Transillumination of the anterior segment aids in detecting opacities and in demonstrating atrophy or hypopigmentation of the iris; these latter signs are important when ocular albinism is suspected. When necessary, fluorescein dye can be used to aid in diagnosing abrasions, ulcerations, and foreign bodies.

Biomicroscopy (Slit-Lamp Examination).

This provides a highly magnified view of the various structures of the eye and an optical section through the media of the eye—the cornea, aqueous humor, lens, and vitreous. Lesions can be identified and localized according to their depth within the eye; the resolution is sufficient to detect individual inflammatory cells in the aqueous and vitreous. With the addition of special lenses and prisms, the angle of the anterior chamber and regions of the fundus also can be examined with a slit lamp. Biomicroscopy is often crucial in trauma and in examining for iritis. It is also helpful in diagnosing many metabolic diseases of childhood.

Fundus Examination (Ophthalmoscopy).

This is best done with the pupil dilated unless there are neurologic or other contraindications. Tropicamide (Mydriacyl), 0.5–1%, and phenylephrine (Neo-Synephrine), 2.5%, are recommended as mydriatics of short duration. These are safe for most children, but the possibility of adverse systemic effects must be recognized. For very small infants, more dilute preparations may be advisable. Beginning with posterior landmarks, the disc and the macula, the four quadrants are systematically examined by following each of the major vessel groups to the periphery. More of the fundus can be seen if a child is directed to look up, down, right, and left. Even with care, only a limited amount of the fundus can be seen with a direct or handheld ophthalmoscope. For examination of the far periphery, an indirect ophthalmoscope is used, and full dilation of the pupil is essential.

Refraction.

This determines the refractive state of the eye—the degree of nearsightedness, farsightedness, or astigmatism. Retinoscopy provides an objective determination of the amount of correction needed and can be performed at any age. In young children, it is best done with cycloplegia. Subjective refinement of refraction involves asking patients for preferences in the strength and axis of corrective lenses; it can be accomplished in many school-aged children. Refraction and determination of visual acuity with appropriate corrective lenses in place are essential steps in deciding whether or not a patient has a visual defect or amblyopia. Photoscreening cameras aid ancillary medical personnel in screening for abnormal refractive errors in preverbal children. The accuracy and practical usefulness of these devices are still being investigated.

Tonometry.

This measures intraocular pressure; it may be performed with a portable, stand-alone instrument or by the applanation method with the slit lamp. Alternative methods are pneumatic and electronic tonometry. When accurate measurement of the pressure is necessary in a child who cannot cooperate, it may be performed with sedation or general anesthesia. A gross estimate of pressure can be made by palpating the globe with the index fingers placed side by side on the upper lid above

the tarsal plate.

Chapter 611 - Abnormalities of Refraction and Accommodation

Emmetropia is the state in which parallel rays of light come to focus on the retina with the eye at rest (nonaccommodating). Such an ideal optical state is common, but the opposite condition, ametropia, often exists. Three principal types occur: hyperopia (farsightedness), myopia (nearsightedness), and astigmatism. The majority of children are physiologically hyperopic at birth, but a significant number, especially those born prematurely, are myopic, and they often have some degree of astigmatism. With growth, the refractive state tends to change and should be evaluated periodically.

Measurement of the refractive state of the eye (refraction) can be accomplished objectively and subjectively. The objective method involves focusing a beam of light from a retinoscope onto a patient's retina through lenses of various powers placed in front of the eye. This method is precise and can be carried out at any age because it requires no response from a patient. In infants and children, it is best done after instillation of eye drops that produce *mydriasis* (dilatation of the pupil) and *cycloplegia* (relaxation of accommodation); those used most commonly are tropicamide (Mydriacyl), cyclopentolate (Cyclogyl), homatropine hydrobromide, and atropine sulfate. The subjective method involves placing various lenses in front of the eye and having the patient report which lenses provide the clearest image of the letters on the chart. This method depends on a patient's ability to discriminate and communicate, but it can be used for some children and can be helpful in determining the best refractive correction for children who are developmentally capable.

Hyperopia.

If parallel rays of light come to focus posterior to the retina with the eye in a state of rest (nonaccommodating), hyperopia or farsightedness exists. This may result because the anteroposterior diameter of the eye is too short, because the refractive power of the cornea or lens is less than normal, or because the lens is dislocated posteriorly.

In hyperopia, accommodation is used to bring objects into focus for both far and near gaze. If the accommodative effort required is not too great, the child has clear vision and is comfortable with both distant and close work. In high degrees of hyperopia requiring greater accommodative effort, vision may be blurred, and the child may complain of eyestrain, headaches, or fatigue. Squinting, eye rubbing, and lack of

interest in reading are frequent manifestations. If the induced discomfort is great enough, a child does not make an effort to see well and may develop bilateral amblyopia (ametropic amblyopia). Esotropia may also be associated (see discussion on convergent strabismus, accommodative esotropia, in Chapter 614). Convex lenses (spectacles or contact lenses) of sufficient strength to provide clear vision and comfort are prescribed when indicated. Even children who have high degrees of hyperopia but who have good vision will happily wear glasses because they provide comfort by eliminating the excessive accommodation required to see well. Preverbal children should also be given glasses for high levels of hyperopia to prevent the development of esotropia or amblyopia. Children with normal levels of hyperopia do not require correction in the majority of cases.

Myopia.

In myopia, parallel rays of light come to focus anterior to the retina. This may result because the anteroposterior diameter of the eye is too long, because the refractive power of the cornea or lens is greater than normal, or because the lens is dislocated forward. The principal symptom is blurred vision for distant objects. The far point of clear vision varies inversely with the degree of myopia; as the myopia increases, the far point of clear vision comes closer. With myopia of 1 diopter, for example, the far point of clear focus is 1?m from the eye; with myopia of 3 diopters, the far point of clear vision is only ??m from the eye. Thus, myopic children tend to hold objects and reading matter close, prefer to be close to the blackboard, and may be uninterested in distant activities. Frowning and squinting are common, because the visual acuity is improved when the lid aperture is reduced; the effect is similar to that achieved by closing or “stopping down” the aperture of the diaphragm of a camera.

Myopia is infrequent in infants and preschool children. It is more common in preterm infants and in infants with a history of retinopathy of prematurity. A hereditary tendency to myopia is also observed, and children of myopic parents should be examined at an early age. The incidence of myopia increases during the school years, especially during the preteen and teen years. The degree of myopia also increases with age during the growing years.

Concave lenses (spectacles or contact lenses) of appropriate strength to provide clear vision and comfort are prescribed. Changes are usually needed periodically, sometimes in 1–2 yr, sometimes every few months. Excessive accommodation during near work has been considered by some to lead to progression of myopia. Based on this philosophy, some practitioners advocate the use of cycloplegic agents, bifocals, intentional undercorrection of myopic refractive errors, or mandatory removal of myopic glasses for near work in an effort to retard the progression of myopia. The value of such treatment has not been scientifically proved.

In most cases, myopia is not a result of pathologic alteration of the eye and is referred to as simple or physiologic myopia. Some children may have pathologic myopia, a rare condition caused by a pathologically abnormal axial length of the eye; this is usually associated with thinning of the sclera, choroid, and retina and often with some degree of uncorrectable visual impairment. Tears or breaks in the retina may occur as it becomes increasingly thin, leading to the development of retinal detachments. Myopia may also occur as a result of other ocular abnormalities, such as keratoconus, ectopia lentis, congenital stationary night blindness, and glaucoma and is also a major feature of the *Stickler syndrome*.

Astigmatism.

In astigmatism, the refractive power of the various meridians of the eye differs. Most cases are caused by irregularity in the curvature of the cornea; some astigmatism results from changes in the lens. Mild degrees of astigmatism are common and may produce no symptoms. With greater degrees, there may be distortion of vision. To achieve a clearer image, a person with astigmatism uses accommodation or frowns or squints to obtain a pinhole effect. Symptoms include eyestrain, headache, and fatigue. Eye rubbing, indifference to schoolwork, and holding reading matter close are common manifestations in childhood. Cylindric or spherocylindric lenses are used to provide optical correction when indicated. Glasses may be needed constantly or only part time, depending on the degree of astigmatism and the severity of the attendant symptoms. In some cases, contact lenses are used.

Infants and children with corneal irregularity resulting from injury, periorbital and eyelid hemangiomas, and ptosis are at increased risk for astigmatism and attendant amblyopia.

Anisometropia.

When the refractive state of one eye is significantly different from the refractive state of the other eye, anisometropia exists. If uncorrected, one eye may always be out of focus, leading to the development of amblyopia, or lazy eye. Early detection and correction are essential if normal visual development in both eyes is to be achieved.

Accommodation.

During accommodation, the ciliary muscle contracts, the suspensory fibers of the lens relax, and the lens assumes a more rounded shape to bring rays of light into focus on the retina. The amplitude of accommodation is greatest during childhood and gradually diminishes with age. The physiologic decrease in accommodative ability that occurs with age is called *presbyopia*.

Disorders of accommodation in children are relatively rare. Premature presbyopia is occasionally encountered in youngsters. The most common cause of paralysis of accommodation in children is intentional or inadvertent use of cycloplegic substances, topically or systemically; included are all the anticholinergic drugs and poisons, as well as plants and plant substances having these effects. Neurogenic causes of accommodative paralysis include lesions affecting the oculomotor nerve (3rd cranial nerve) in any part of its course. Differential diagnosis includes tumors, degenerative diseases, vascular lesions, trauma, and infectious diseases. Systemic disorders that may cause impairment of accommodation include botulism, diphtheria, Wilson disease, diabetes mellitus, and syphilis. Adie tonic pupil may also lead to a deficiency of accommodation after some viral illnesses (see Chapter 613). Rarely, inability to accommodate is caused by a congenital defect of the ciliary muscle. An

apparent defect in accommodation may be psychogenic in origin; it is common for a child to feign inability to read when it can be demonstrated that visual acuity and ability to focus are normal.

Chapter 612 - Disorders of Vision

Amblyopia.

Amblyopia is the decrease in visual acuity, unilateral or bilateral, that occurs in visually immature children as a result of a lack of a clear image falling on the retina. The unformed retinal image may occur secondary to a deviated eye (strabismic amblyopia), an unequal need for vision correction between the eyes (anisometropic amblyopia), a high refractive error in both eyes (ametropic amblyopia), or a media opacity within the visual axis (deprivation amblyopia).

Under normal conditions, the development of visual acuity proceeds rapidly in infancy and early childhood. Anything that interferes with the formation of a clear retinal image during this early developmental period can produce amblyopia. Amblyopia may occur only during the critical period of development, before the cortex has become visually mature, within the first decade of life. The younger a child, the more susceptible he or she is to the development of amblyopia.

The *diagnosis* of amblyopia is confirmed when a complete ophthalmologic examination reveals reduced acuity that is unexplained by an organic abnormality. If the history and ophthalmologic examination do not support the diagnosis of amblyopia in a child with poor vision, consideration must be given to other causes (i.e., neurologic, psychologic). Amblyopia is usually asymptomatic and detected only by screening programs. Screening is easier in older children. However, just as amblyopia is less likely to occur in an older child, it is also more resistant to treatment at that age. Amblyopia is reversed more rapidly in younger children whose visual system is less mature, although screening is more difficult. The key to the successful treatment of amblyopia is early detection and prompt intervention.

Treatment generally first consists of removing any media opacity or prescribing appropriate glasses, if needed, so that a well-formed retinal image can be produced in each eye. The sound eye is then covered (occlusion therapy) or blurred with glasses or drops (penalization therapy) to stimulate proper visual development of the more severely affected eye. In many cases, best results are achieved with complete and constant occlusion throughout the waking hours by the use of adhesive eye patches; in some cases, part-time occlusion is sufficient or preferred. Occluders placed on spectacles allow peeking, and the adjustable headband type of cloth or plastic occluder is too easily removed by a child. In selected cases, an opaque contact lens or a contact lens of sufficiently high power to blur the vision in the better eye is used. Most children and their families tolerate occlusion therapy well. In some cases, a child resists therapy because of the severity of the vision defect, the cosmetic blemish of the patching, or related psychologic disturbances. The goals of

treatment must be thoroughly understood and the treatment carefully supervised. Close monitoring of amblyopia therapy is essential, especially in the very young, to avoid deprivation amblyopia in the good eye. Many families need reassurance and support throughout the trying course of treatment.

Diplopia.

Diplopia, or double vision, is most frequently a result of malalignment of the visual axes, for example, displacement or deviation of the eye. It is common in heterophoria, in heterotropia of recent onset (particularly when caused by acquired nerve palsy), and in proptosis. Occluding one eye relieves the diplopia; affected children commonly squint, cover one eye with a hand, or assume abnormal head postures (a face turn or head tilt) to alleviate the bothersome sensation. These mannerisms, especially in preverbal children, are important clues to diplopia. The onset of diplopia in any child warrants prompt evaluation; it may signal the onset of a serious problem such as increased intracranial pressure, a brain tumor, an orbital mass, or myasthenia gravis.

Monocular diplopia results from dislocation of the lens, cataract, or some defect in the media or macula.

Suppression.

In the presence of strabismus, diplopia occurs secondary to the same image falling on two different regions of the retina. In a visually immature child, a process that may occur in the cortex eliminates the disability of seeing double. This active process is termed *suppression*, and it occurs only in children. Although suppression eliminates the annoying symptom of diplopia, it is the potential awareness of a second image that tends to keep eyes properly aligned. Once suppression develops, it may allow an intermittent strabismus to become constant or strabismus to redevelop later in life even after successful treatment during childhood.

Amaurosis.

Amaurosis is partial or total loss of vision; the term is usually reserved for profound impairment, blindness, or near blindness. When amaurosis exists from birth, primary consideration in differential diagnosis must be given to developmental malformations, damage consequent to gestational or perinatal infection, anoxia or hypoxia, perinatal trauma, and the genetically determined diseases that can affect the eye itself or the

visual pathways (Table 612–1). In certain cases, the reason for amaurosis can be readily determined by objective ophthalmic examination; examples are severe microphthalmia, corneal opacification, dense cataracts, chorioretinal scars, macular defects, retinal dysplasia, and severe optic nerve hypoplasia. In some cases, an intrinsic retinal disease may not be apparent on initial ophthalmoscopic examination; an example is **Leber congenital retinal amaurosis**. In this retinal dystrophy, the fundus may appear normal or near normal for some time before ophthalmoscopically appreciable signs of retinal degeneration (e.g., pigmentary deposits, arteriolar attenuation, optic disc pallor) develop. In such cases, electroretinography is important in diagnosis, because the electroretinographic response in this condition is markedly reduced or absent. In many cases of amaurosis, the defect lies not in the eye or optic nerve but in the brain, requiring neurologic and neuroradiologic evaluation, including CT or MRI.

Amaurosis that develops in a child who once had useful vision has different implications (see Table 612–1). In the absence of obvious ocular disease (e.g., cataract, chorioretinitis, retinoblastoma, retinitis pigmentosa), consideration must be given to many neurologic and systemic disorders that can affect the visual pathways. Amaurosis of rather rapid onset may indicate an encephalopathy (hypertension), infectious or parainfectious processes, vasculitis, migraine, leukemia, toxins, or trauma. It may be caused by acute demyelinating disease affecting the

TABLE 612-1 -- **Etiologies of Childhood Amaurosis (Blindness)**

Congenital
Optic nerve hypoplasia or aplasia
Optic coloboma
Congenital hydrocephalus
Hydranencephaly
Porencephaly
Micrencephaly
